Address in Medicine.—Dr. Philip H. Pye-Smith then delivered the annual address in medicine, taking as his subject "Medicine as a Science and Medicine as an Art." He said that medicine was defined by Aristotle as the art of healing and the art of curing, and to this might be added the art of preventing disease. Nevertheless, as the art of agriculture rested on botany, geology, and vegetable physiology, so the art of medicine depended on the science of pathology, the practice of physic, and the principles of physic. It must never be forgotten that it was an art. Theories, or what seem to be logical deductions, or explanations, or statistics, or authority, must never be allowed to take the place of observation and experience. The disease must never be treated without considering the patient. There need be no wonder if vast knowledge, profound learning, and the best scientific training sometimes failed to make a successful practitioner, for besides adequate knowledge and a strenuous effort to do the best for each individual patient there was ample room for the personal qualities which insured success in every department of life—power of observation and insight—the personal influence by which a strong character would secure obedience and inspire hope, the judgment which divined what kind of remedies were suited to each patient, and the sympathy which put one in the patient's place, and not only met but anticipated his wants. If, however, medical science without art was inefficient, medical art without science was not only unprogressive, but almost always became quackery. As soon as patients were treated by rule of thumb, by tradition, by dogmas, or by metaphysical axioms, injury was done to the physician and to the patient. Bonesetters ignorant of anatomy, wise women who cured by charm, were irrational; the indiscriminate use of "tonics" was as irrational as that of hydrotherapy, of alcoholic stimulation, or of electricity. There was no such thing as a tonic or strengthening medicine: the sole source of strength was oxidizable food, and bitter medicines could only give strength by improving the appetite. The last of the systems of medicine founded on a dogma was homœopathy. Apart from these exploded systems of treatment, our profession had often suffered from lack of the scientific, inquiring, sceptical spirit, and had been led too easily by authority, by tradition, and by fashion—as witness the past abuse of venesection and of mercury. The important and constantly growing branch of medicine which dealt with the prevention rather than the cure of disease also depended upon science, for tracing the dependence of one event upon another was the essence of inductive science. How closely natural science was related to preventive medicine was shown by the history of Jenner, who was a naturalist, and Pasteur, who was a chemist. We ought to give up the perfunctory explanations which so often did duty for investigation, and not ascribe every inflammation to cold, every doubtful symptom to gout, disease to overwork and worry; modern life was easier and safer and smoother than it was a hundred years ago, and young men and maidens were healthier, better grown, less emotional than their great-grandparents. The duty of a physician was not to flatter the selfishness of neurotic patients, but to inspire fortitude, and to prescribe regular and steady work as the best cure for a thousand nervous ailments. There was another temptation—and that was to assume that because many diseases were now proved to depend upon the presence of bacteria this must be true of all. Science did not anticipate, but waited for proof. Another important branch of medicine—prognosis—depended as an art upon experience and insight. Yet here also rational prognosis rested on the science of statistics. Statistics must be based upon cases which were both numerous and accurate. It was only after hundreds of cases had been observed that it was learned that infantile paralysis sometimes befell adults, and that osteo-arthritis might occur in children. This paucity might be remedied by time, but the defect of inaccuracy was without remedy. If diagnosis was perfunctory or careless, and nomenclature arbitrary and inconstant, the more cases were observed the less did they teach. The necessity for experiments for the progress of pathology and for the cure and prevention of disease was too important to be omitted. As its objects and methods were better understood, it would secure the enlightened patronage of all who desired the improvement of human knowledge and the increase of human happiness. The cure of disease rested upon science, but even in its practical carrying out we were bound to take with us a scientific spirit. Some men prescribed, and never saw that the prescriptions or directions were carried out. How could success be expected in treating an obscure nervous affection if galvanism was applied to the spine without making sure of any physiological effect—nay, sometimes without making sure that a current was passing through the electrodes; or if a patient was sent to drink the waters of a fashionable watering-place without the physician remembering that there were two or perhaps three springs, one of them inert and another possibly injurious? What success could be anticipated if ointment was ordered for a weeping eczematous patch when it floated on the secretion and never reached the inflamed tissue, or if a lotion was prescribed to be applied twice a day to a skin well protected by its sebaceous secretion? Much ineffectual treatment again depended upon want of confidence in one's diagnosis. If syphilis was only suspected, remedies would be given in inadequate doses. Another source of failure in therapeutics was the legion of new remedies. It was astonishing to find apparently rational men forsaking the drugs which had been proved effectual by the experience of long-past time in all nations, to take up with remedies the composition of which was often unknown, the use of which they had never learned, and of which the value rested upon the interested or credulous assertions of those who were trying to sell them. A scientific spirit should also be more freely admitted in treatment by baths and waters. Was a bath different in its effects because it came heated from the earth rather than from a kettle, or did salts act differently when occurring in natural solution than when dissolved in the same proportion in the

druggist's shop? It should be frankly acknowledged that benefit was derived by change of air and scene, by early hours, regulated rest, exercise, diet, and copious draughts of water. Was it not also a mistake to prescribe made-up drugs, and thus lead patients to ascribe their recovery not to the doctor's skill, but to this or that pill or tablet? As to the physician's just recognition, his patients could not be expected to understand the scientific basis of medicine, nor, as his services were to the individual and not to the community, could he expect the rewards given to statesmen, generals, or judges; but he did as a rule receive the trust, the honor, and the gratitude which he had earned, for patients understood personal character, honesty, sense, kindness and sympathy, liberality, and benevolence to rich and poor.

Award of the Middlemore Prize.—After a vote of thanks to Dr. Pye-Smith had been passed, the president announced that the Middlemore prize, of the value of £50, had been awarded for research in ophthalmology to Dr. Ernest Maddox, of Bournemouth.

Reform in the Association.—The reports of the parliamentary bills committee, of the scientific grants committee, of the general practitioners and ethical committee, of the anæsthetics committee, and of the therapeutic committee having been presented and adopted, Mr. Victor Horsley presented a resolution, "That a committee be appointed to consider and report upon the best means of reorganizing the constitution of the British Medical Association, such committee to furnish a provisional report to the branches by March 1, 1900." In speaking upon the motion he sketched the reforms which he thought necessary, and read a list of twenty-three names of men who, he said, ought to constitute the committee. After the members had recovered their breath they decided that Mr. Horsley was not the whole association, and that the others should have some voice in the matter. It was then decided that the committee should consist of twenty-four members, twelve to be nominated by the council and twelve by the general body, and that the appointment should be made at the next general session. The resolution was then carried, the date for the provisional report being advanced to February 1st, in order to allow time for consideration of the proposed changes by the Australian branches.

SECTION OF SURGERY.

First Day—Wednesday, August 1st.

President's Address.—Mr. Howard Marsh, of London, in opening the work of the section, said that, in accordance with a general agreement, he would make no formal address, but would briefly call attention to the work which had been planned for this meeting. An effort had been made to limit the number of papers, and so prevent the congestion that usually occurred and allow time for the intelligent discussion of the subjects introduced. There would be two set discussions, one on subphrenic abscess, the other on fractures. It might be thought that one of these conditions was too uncommon, the other too common to merit formal discussion by the members of the section, but this was not so. Subdiaphragmatic abscess was not such a rare condition as was generally supposed, and there had been many improvements in the diagnosis and treatment of fractures in recent years which would well bear discussion at the present day.

Subdiaphragmatic Abscess.—Mr. Rickman J. Godlee, of London, opened the discussion with a long and carefully considered paper. The condition, he said, was not a disease but a symptom, and he would define it as "a collection of pus, with or without gas, between the diaphragm and the structures in contact with it." There were no pathognomonic symptoms of the affection, a pleuritic stitch and hiccough being perhaps the most common. If there was no gas present, the percussion note would be dull when the abscess was near the surface, but in cases of subdiaphragmatic pneumothorax (as the condition had been called when gas was present) the note would be tympanitic. The respiratory movements of the chest were seldom interfered with, and the normal pulmonary sounds were generally audible—signs of value in the differential diagnosis. The speaker then presented an etiological classification of the different forms of subphrenic abscess, in which he said he had followed Maydl quite closely. This was as follows: (1) *Stomach.*—In cases of sudden perforation of a gastric ulcer the pus might escape into the general peritoneal cavity or into the smaller sac, but in either case it was not uncommon to find it localized. In other cases in which the perforation of the stomach walls was gradual, adhesions were almost always formed with the diaphragm or adjacent viscera, and a strictly circumscribed subphrenic abscess was sometimes the result. More often, however, these abscesses burrowed widely, and in such cases a diagnosis of empyema (especially if, as not infrequently happened, there was a coincident pleural serous effusion) was often made. (2) *Intestine.*—Subdiaphragmatic abscesses of intestinal origin were the result of perforation of ulcers of the duodenum or transverse colon. In such cases gas was mingled with the pus and the note elicited by percussion was tympanitic, though if the patient were made to stand, some dulness might be obtained at the lower portion of the collection. (3) *Appendix.*—A subphrenic abscess might result from the migration of a perityphlitic abscess. In such cases there was first a swelling in the iliac fossa, which usually subsided as the signs of a subdiaphragmatic collection became pronounced. The abscess might be on the left side, though naturally it was more commonly on the right. (4) *Hydatids.*—Suppuration might occur in an hydatid cyst of the liver or spleen. (5) *Liver.*—As would be expected, many subdiaphragmatic abscesses owed their origin to disease of the liver or gall tracts, a perihepatic abscess being a not very uncommon affection. (6) *Kidneys.*—Occasionally a perirenal abscess was formed between the kidney and the diaphragm, and sometimes a subphrenic abscess was simulated by a pyonephrosis of large size. (7) *Subcutaneous Injuries.*—Cases were on record in which a subdiaphragmatic abscess had followed a blow without a wound of the skin, but it was probable that in such instances an ulcer of the stomach or intestine had been present and the blow caused perforation. (8) *Wounds.*—Septic material might be introduced in the case of a penetrating wound of the abdomen and lead directly to the formation of an abscess. (9) *Metastases.*—Maydl had this division in his classification, but the speaker was inclined to regard the abscesses grouped under this head as due in reality to direct extension of pus from some lesion in the neighborhood. (10) *Ribs.*—Cold abscesses resulting from necrosis or caries of the ribs might burrow through the muscular tissues and become subphrenic in location. (11) *Thorax.*—The pus of an empyema or that resulting from Pott's disease or mediastinitis might pass down beneath the diaphragm. (12) *Various Causes.*—This was Maydl's last group, and included tuberculosis, pancreatitis, peritonitis, and actinomycosis. The last-named condition was seemingly not so rare as was generally supposed, for the speaker had seen no fewer than thirteen cases in the past five years. The matter forming the contents of the so-called abscess in cases of actinomycosis was not true pus. The progress of these cases was very slow, and the treat-

ment was not entirely satisfactory in its results. In those cases in which the subdiaphragmatic abscess resulted from perforation of a gastric or intestinal ulcer it was often necessary to close the opening in the viscus, though sometimes simple drainage of the abscess cavity was sufficient.

Mr. Bruce Clarke, of London, spoke of the diagnosis, which he said was usually difficult and could often be made only by exclusion. Among the causes he regarded a perforating ulcer of the stomach or intestine as by far the most common. He agreed with Mr. Godlee that it was incorrect to speak of metastasis as one of the causes of subdiaphragmatic abscess, and preferred the term "septic condition." He favored the making of an incision in the abdomen large enough to admit the hand for exploratory purposes, before cutting directly into the abscess.

Mr. Leonard A. Bidwell, of London, reported six cases of subphrenic abscess, in four of which a diagnosis of empyema had been made. Gastric ulcer was the cause in three cases and ulcer of the transverse colon in one. He spoke of the odor of the pus in cases of subphrenic abscess, which was peculiarly offensive and served as a diagnostic point in the differentiation from empyema.

Mr. Edward Barnard Fuller, of Cape Town, said that a bacteriological examination of the pus removed by an exploratory aspiration was often of great service in the way of diagnosis, the presence of the colon bacillus pointing with almost absolute certainty to the intestinal origin of the abscess and consequently establishing the diagnosis of subphrenic abscess as opposed to empyema.

Interesting cases of subdiaphragmatic abscess were reported by Mr. James Stanley Boyd and Mr. Noble Smith of London, Dr. Cameron of Canada, Dr. Lennander of Upsala, Mr. Firmin Cuthbert of Gloucester, and Mr. R. C. Chicken of Nottingham.

Pyloroplasty.—Mr. Leonard A. Bidwell, of London, reported a number of cases of non-malignant stenosis of the pylorus in which he had performed pyloroplasty with excellent results, and he regarded the operation in such cases as one attended with comparatively slight risk.

Prof. John Berg, of Stockholm, said his experience with pyloroplasty had not been entirely satisfactory, retraction of the stenosis having occurred in about half of his cases. He was obliged to resort to gastro-enterostomy in these cases, and usually now had recourse to this operation in the first instance as being the more sure in its results and not much more dangerous. He said it was not safe to tabulate the results of a pyloroplasty within three years of the operation, since recurrence of the stricture was sometimes very late.

Cholecystocolostomy.—Mr. Henry Betham Robinson, of London, reported a case of jaundice due to obstruction of the ductus communis choledochus by a syphilitic formation. An anastomosis was established between the colon and the gall bladder, and potassium iodide was administered. The patient made a good recovery, and the stricture was eventually relieved.

Oöphorectomy in Mammary Carcinoma.—Mr. J. Stanley Boyd read a paper in which he had collected the statistics of thirty-eight cases of this operation—all of which he could find mention in the literature up to the present time. In seventeen of these cases (nearly forty-five per cent.) the operation had been followed by improvement in the condition of the breast. In some of the cases thyroid feeding had also been resorted to, but the speaker did not think there was any evidence of benefit from this. The operation was still *sub judice*, but enough had been learned to show that it was useless to resort to it after the menopause.

Stricture of the Rectum.—Mr. Frederick Charles Wallis, of London, read a paper on the etiology and treatment of non-cancerous stenosis of the rectum. In almost all of these cases, he said, some toxæmic condition was present, as shown by the frequent coincidence of arthritis. Excision of the strictured portion of the gut, with pulling down of the mucous membrane and suture to the anus, was a method of treatment to which he had resorted with most satisfactory results in two cases, the histories of which he narrated.

Mr. Frederick Treves, of London, said that the operation of excision was of use only in cases of fibrous stenosis of the rectum, but in selected cases it was often of great benefit. He believed that many cases of rectal stricture, although not recognized until later in life, were really of congenital origin.

SECTION OF GENERAL MEDICINE.

First Day—Wednesday, August 1st.

The medical section met in the Art Gallery, Wednesday forenoon, under the presidency of Dr. Thomas Buzzard. The president said that complaints were often heard that the chairman's introductory address took up too much time that might more profitably be devoted to the scientific work of the section, and he would therefore content himself with a few informal remarks.

Influenza as it Affects the Nervous System.—The set discussion on this subject was opened by Dr. Judson S. Bury, of Manchester. He said that influenza was such a protean disease that it was almost impossible to picture any typical syndrome, and while four general forms might be recognized according as the symptoms were referable chiefly to the respiratory, the gastro-enteric, the cardiac, or the nervous apparatus, yet in all the nervous system was a special sufferer from the action of the toxin. Of the nervous form *par excellence* there were two divisions, embracing (1) cases in which the brain was chiefly affected, and (2) those in which the symptoms were of a mental, neurasthenic, or paralytic order. Cases in the first group, in which the most characteristic symptom was delirium or coma, occurred during the pyrexia, those of the second group were not marked by fever. The difference between the influenza and the diphtheria toxins, as regarded their influence upon the nervous system, was that the former seized upon no special part of the nervous system, but affected now one, now another portion, seemingly at haphazard. In the polyneuritis of influenza he thought it possible that the active agent might be a streptococcus or some other as yet unrecognized pathogenic agent, the influenza bacillus acting only as a forerunner preparing the soil for the specific germ. He reported several cases of nervous influenza in illustration of the various points brought out in his communication.

Sir William Broadbent, of London, thought a distinction should be made between the direct action of the bacilli upon the tissues and that of their toxins. The more serious forms, the comatose and delirious types of the preceding speaker, were probably due to the direct action of the bacilli, being analogous to pernicious malarial fever of cerebral type in which were found plasmodial and leucocytic emboli in the vessels. In the neuritic and neurasthenic cases, on the other hand, the symptoms were probably the effect of the toxin of the disease acting upon some already weakened spot. The speaker reported several interesting cases: one of acute dementia following influenza, six of the acute comatose form, and one of polyneuritis in which death occurred after involvement of the respiratory muscles. In one case, probably of thrombosis of the cerebral vessels of the right side, the patient suffered from hemiplegia of gradual onset and still more gradual decline; the attack occurred

ten years ago, and now the hemiplegia had almost entirely disappeared. In another case, which had ended in recovery, there were very severe unilateral convulsions, without paralysis.

Sir Peter Eade, of Norwich, was unable to agree with Sir William Gowers, who had said that the influenza poison affected chiefly the motor nerves, and believed that its incidence was rather on the sensory apparatus. The medulla oblongata was the part mainly attacked, and in this the speaker saw an explanation of the frequent cardiac complications. He thought it incorrect to call the nervous symptoms sequelæ, for he believed the implication of the nervous system began during the primary attack. He remarked upon the unexampled duration of the present pandemic of the disease, which had now lasted ten years.

Dr. T. Clifford Allbutt, of Cambridge, said that many cases were called influenza incorrectly, and he insisted upon the necessity for accuracy in diagnosis. One sign of value in this respect was the sudden onset of the disease. He thought the anterior part of the brain was the most frequently attacked, but whether certain areas here were more liable to involvement than others he could not say, though it would be well to determine this point. In cases in which the symptoms pointed to lesions of the central nervous system he advocated lumbar puncture in order to render possible a bacteriological diagnosis. He thought the prognosis of nervous influenza was not favorable. He related a case in which there had been aphasia and paralysis; the latter had disappeared completely, but the patient suffered from aphasia whenever he attempted to talk fast.

Dr. Newton Pitt, of London, questioned whether the meningitis and other severe nervous affections associated with influenza were due to the direct effect of the specific bacillus. He had seen several cases in which typhoid fever followed an attack of influenza, but no one would claim that the typhoid lesions were influenzal; the influenza bacilli had doubtless overcome the resisting power of the organism, which had then become vulnerable to the action of the typhoid germ, and it might be the same in the so-called influenzal meningitis. He had, however, found Pfeiffer's bacillus in a couple of cases in which the inflammation had crept up through the nasal sinuses. He held that the cardiac forms of influenza were really nervous, the heart suffering through its nerve supply and not from myocardial implication. In many cases also the symptoms referable to the heart were really secondary to gastric disturbances. In polyneuritis of influenzal origin facial paralysis was a common symptom.

Dr. Frank M. Pope, of Leicester, thought it not improbable that the incidence of the influenzal poison might often be determined by trauma, and related a case of comatose type seeming to support this assumption. He remarked upon the fact that the nervous forms of influenza were more common at the beginning of the epidemic than now, and thought this was due to the fact that those whose nervous system was vulnerable speedily fell victims, thus showing that the disease attacked the weak spots. He referred to cases of anosmia as being of unfavorable prognosis, and explained this by the fact that the olfactory centre was so close to the nasal mucous membrane, the portal of entry of the disease, that it received a large dose of the poison.

Dr. J. M. MacCormac, of Belfast, said that one spoke always of the influenza bacillus, and of influenza as a specific entity, but he questioned very much whether such a protean disease as that called influenza could really be due to the action of only one form of bacillus.

Dr. S. K. Mullick, of London, thought influenza was primarily a disease of the nervous system, the other organs and apparatus being secondarily affected, and of the nervous system the motor nerves were more commonly involved than the sensory.

Dr. S. E. Solly, of Colorado Springs, reported a case of influenzal hemiplegia terminating in recovery.

Dr. R. Saundby, of Birmingham, spoke of diabetes following influenza, which he said was exactly comparable to diabetes following any other acute infectious malady, and was not improbably due to a chronic interstitial pancreatitis set up by the toxin of the disease.

Dr. Garrett Anderson, of London, agreed with Dr. Clifford Allbutt as to the necessity for accurate diagnosis, and said that influenza was too often used as a convenient term to cover ignorance. She reported two cases of influenzal diabetes. Referring to the interesting series of cases reported by Sir William Broadbent, six of which occurred on a training-ship, she said that the poison was intensified by crowding; and she herself had observed similar aggregations of cases in the servants' quarters of great houses and in schools.

Dr. John Haddon, of Hawick, believed that influenzal pneumonia was due to an early implication of the vagus centres.

Dr. William Ewart, of London, spoke of the differential diagnosis of the influenzal imitation of the system diseases (such as tabes dorsalis, Friedreich's ataxia, and spastic paraplegia) and system diseases with organic lesions. In the former the symptoms were of sudden onset, the disease appeared at once in full intensity and then began to subside gradually; in the true disease the beginning was insidious and the symptoms increased very gradually in intensity. He recommended especially a study of the nervous forms of influenza, for he thought we might through this increase our knowledge of the mode of action of the various toxins upon the brain and spinal cord. In certain cases of recurring influenza or of nervous symptoms appearing some time after the subsidence of the primary attack, the speaker thought it possible that the bacilli might be persisting in the nasal mucous membrane or elsewhere and giving forth continually fresh supplies of toxin.

Sir John William Moore, of Dublin, said that in his opinion many cases of so-called influenzal nervous disorders were purely imaginary. Influenza frequently induced a peculiar psychical state in which the patients became hypochondriacal and imagined themselves the subject of various serious diseases, when, as a matter of fact, they had no organic lesions whatever. As to the cardiac form of influenza, he agreed with Dr. Newton Pitt that the symptoms were more often of nervous than of myocardial origin.

Dr. St. Clair Thomson, of London, referred to influenzal anosmia, and said he did not regard the prognosis as especially unfavorable. He advocated cleansing of the nasal mucous membrane, but doubted the utility of strong antiseptic solutions. He spoke also of influenzal paralysis of the larynx and of the pharyngeal hyperæsthesia occurring in this disease.

Dr. Thomas Buzzard, of London, the president of the section, said that we ought to distinguish between the symptoms actually due to influenza and those of the diseases which were pre-existing and had only been brought to light by the influenzal attack. As an example of the latter, he reported a case of locomotor ataxia in which the symptoms, previously slight, were greatly intensified after an attack of influenza. Similarly in many cases of influenzal mania and melancholia there was doubtless mental disease smouldering beneath the surface and only needing the disturbing influence of the acute infection to burst into flame. He referred to some earlier writings in which he had

noted the bizarre arrangement of the symptoms of syphilis of the nervous system, such as paralysis of a leg and an arm on opposite sides of the body, an arrangement which was now recognized as the result of the action of toxins. This same bizarre arrangement was seen in the symptoms of nervous influenza, showing that they were the expression of a toxæmia. In illustration of this the speaker reported several cases of unusual interest. One patient had double optic neuritis, nystagmus, paralysis of both arms and both legs, intention tremor of one arm, and absence of the patellar phenomenon. He said the nomenclature of nervous influenza was too cramped and a wider vocabulary was needed. Toxæmic nervous affections had largely increased of late, and this was in great measure due to the influenza pandemic.

Dr. Bury closed the discussion, giving several illustrations of the value of debates of this sort, showing how they added to the sum of the store of medical knowledge.

(To be Continued.)

Medical Items.

Plague in Oporto. — Dr. Albert Chalmette, writing in the *North American Review*, July, on the plague in Oporto says: "The experiments initiated by the French mission, and conducted with the aid of the Portuguese and foreign doctors present at Oporto, prove unexceptionally that with energetic measures intelligently applied it is easy to arrest the spread of the disease in a district or city. The experiments were first of all directed toward the prevention of the plague among animals susceptible to it and among mankind. The international committee appointed to verify this by the president of the Portuguese council of ministers affirmed that every one who will submit to the inoculation of 5 c.c. of the anti-plague serum of the Pasteur Institute would by such vaccination be protected against the plague for a period of about three weeks, and that it would be of the greatest value if this vaccination were made obligatory . . . The measures that the French scientific mission recommended to the sanitary authorities of Oporto were these: (1) Isolation and the obligatory transportation of those stricken to a special hospital; (2) compulsory vaccination of all persons who have been in contact with the sick or who inhabit the same house; (3) the building of temporary huts to lodge for a period of twenty days all persons who have inhabited a house where a case of plague has occurred; (4) complete disinfection, airing and abandoning for a space of twenty days a house where a case of plague has been observed; (5) the organization as at Bombay, if (as almost always happens) the population conceals cases, of search committees composed of doctors, nurses, litter bearers, and police, which committees, arranged for districts, should visit twice a day all dwelling-places in their quarter and satisfy themselves that no case of illness exists in them; (6) the methodical destruction of rats and mice in the shops, houses, and sewers; (7) liberty of circulation outside the town for all persons who have been vaccinated against the plague within a period of not less than forty-eight hours, nor more than fifteen days, after such vaccination; (8) the burning of buildings of small value where many cases of the disease have occurred."

New Air-Ship.—According to a cablegram in the daily papers, the first authoritative report on Count Zeppelin's airship was made on July 10th at a meeting of the Society for the Promotion of Aerial Navigation by experts who either shared in or watched the recent experiments. They declared that improvements in the steering apparatus were necessary, the one used at present having been thrown out of gear on one side of the balloon, rendering its proper guidance and return to the starting-point impossible. The steering-rods running upward from the car were too weak and became bent. The screw-blades consequently did not respond properly. The air-pressure motors failed, but it was difficult to say whether this was caused by a defect or by bad handling. The method of transmitting power to the screws will need great improvement to enable the airship to contend against even a light wind. During the recent ascent the wind had a velocity of three metres to the height of one hundred metres, and against this the vessel sailed well; but at a height of from one hundred and fifty to two hundred metres the balloon was evidently driven before the wind. It must be remembered, however, that this was when one of the rudders was out of gear. If the speed of the screws cannot be increased, the blades must be enlarged. Another defect was the continual escape of gas, necessitating constant filling up of the receptacle up to the moment of starting. This defect alone will prevent the achievement of the idea of remaining in the air for eight consecutive days, as a single filling costs 1,000 marks. Already more than 1,000,000 marks has been spent on the machine and experiments, of which amount Count Zeppelin furnished about 500,000 marks.—*Science.*

Mr. Treves on Wounds in War.—Mr. Treves, lecturing recently in London on his South African experiences, concludes that operations upon the wounded in battle should be performed under the following circumstances: (1) If the patient is seen before seven hours have elapsed; (2) if the patient has had a short and easy transport; (3) an empty stomach. In anteroposterior wounds of the abdomen above the umbilicus it is a *sine qua non* that the bullet should have escaped. He judges that the circumstances against operation are: (1) As a general rule, if the patient is not seen till more than seven hours after the wound; (2) if there has been a long and arduous transport; (3) all cases of transverse or oblique wounds above the umbilicus, because it is practically impossible to do all that is required, the openings in the bowel and the wounds of other structures being so numerous; (4) all cases of retained bullet; it is impossible in the field to start on a search for the bullet, a procedure that would require bringing the viscera out of the abdomen; (5) all cases of wounds of the liver, of the spleen, and of the kidney; (6) most cases of wound below the umbilicus, because they do all right if let alone; (7) cases in which the colon alone is implicated (perhaps excepting the transverse colon), because these cases do very well if let alone.

British Army Contract Scandals.—So much was written at the time of our war with Spain concerning the shortcomings of our army commissariat department that it is perhaps somewhat excusable on our part not to be too greatly distressed to find that the conduct of the same department of the British army has not been above reproach. London *Truth* says in reference to this matter: "Evidence of a most interesting, not to say sensational, character was given at a late sitting of the committee on army contracts. The story of the boots supplied to the company of the Second V. B. Worcestershire regiment formed for service in South Africa reads like a chapter from the history of the Crimean war. Not only were these boots delivered seventeen or eighteen days after the troops ought to have sailed, but after being tried during a route march to Aldershot were found to be useless rubbish, and one hundred and fifty pairs out of two hundred and twenty

six were actually condemned after being opened and inspected by the representatives of the middleman who took the contract. The worst feature of the case is that for these precious goods the regiment had paid considerably more than the usual government contract price. Within the past few months I have been in direct communication on this subject with two or three firms who have had a large experience of such contracts. All of them agree that in execution of an army contract it is the necessary and usual course to bribe subordinate officials chiefly for two purposes—the passing of the work and the passing of accounts. For instance, one contractor told me that he had an enormous sum—reckoned in tens of thousands of pounds—long outstanding, and his only chance of getting his accounts settled up in reasonable time was to grease the palms of the military foreman of works, who otherwise could and would delay the payment for an indefinite time. One contractor told me that I might take it as certain that, whatever tender is accepted, from ten to fifteen per cent. has been added to the price for the purpose of 'backsheesh.'"

Inhuman Experiments.—The Berlin correspondent of the *British Medical Journal* narrates the following experiments performed on a human being in Germany. He says: "Gross abuses in any profession should not be hushed up, but should rather be made public as freely as possible, so as to rouse public opinion against them and thus render their repetition or spread impossible; and, therefore, we have reason to thank the Social Democrat paper *Vorwärts* for dragging into light the 'experiments' made by Dr. Stubell (first assistant in Professor Stinzing's clinic at Jena) on patients suffering from diabetes insipidus, and published by him in the *Archiv für klinische Medizin*. Dr. Stubell there tells how he kept one of his patients in an attic with barred windows, the door of which he locked, putting the key in his pocket; how the patient, who was allowed only a very small amount of liquid, in his torturing thirst, which is a symptom of the disease, drank his washing-water; how one night in his agony he drank about 1,400 c.c. of his own urine; how another night he wrenched off one of his window bars, climbed over the roof to another small window, through which he crept, thus finding his way to a water-tap, where he was captured and brought back to his prison. Dr. Stubell calmly states that his patient must have endured 'frightful tortures' one night, and gives the following account of his condition in the morning: 'The patient was quite collapsed, his face seemed dried up, eyes and cheeks deeply sunken, pulse almost imperceptible, a great deal of pain, joints stiff.' The whole medical profession must reprobate cruelties such as these perpetrated in the name of science."

A Noble Doctor.—The London *Globe* recently published a letter from a correspondent in the Orange River Colony telling the following story concerning one of the medical officers to the British forces in South Africa: "I wanted to tell about our doctor. He is a splendid chap, named Martin. I believe the fellows simply swear by him. For instance, the other morning I took some men of my command down to see him, and after looking at the sick report, he said: 'Oh, yes! Jorkins, chap with rheumatics in the right leg.' 'Yuss, doctor, pains horful,' says Jorkins. Jorkins is a London cockney, good soldier, and particular friend of mine. 'Well, look here, Jorkins, you must have something warm over you at night; take this overcoat; you must go into hospital when we reach camp.' This overcoat I noticed was the doctor's own private property, and I thought what a good soul he was. Next came Walker. 'Let me see; Walker, bad chest; still painful, eh?' 'Shockin',' tersely answered Walker. Said the doctor, diving into a kit bag, 'take this,' producing a fine woollen shirt, worth its weight in gold out here. 'Rip it up and wrap it round your chest every night, and here's some more cough mixture for you. I can't do anything more for you just now.' I was walking just behind these two as they returned to their lines. 'Proper toff, ain't 'e,' says Jorkins. ''E's wot I call the fine root'; and when a soldier dubs a man the 'fine root' it means a lot." —*Physician and Surgeon.*

State Care of Dependent Children.—Henrietta Christian Wright contributed a well-written article on the above subject to the July number of the *North American Review*, in which she points out that the methods in vogue in New York State and in other States of the Union of grappling with the problem of how best to deal with indigent children are both unintelligent and harmful. She is in favor of the boarding-out system, and cites Massachusetts as a striking example of this mode of procedure carried out successfully. Referring to this State, Miss Wright says: "Massachusetts, with a population to the square mile exceeding that of New York, and in which the artificial conditions of living are practically the same, has no dependent children, technically speaking, in institutions supported by the State. Largely affected by the problem of immigration and under the strain produced by great centres of population engaged in mill and factory work and so removed from the more healthful influences of smaller village and country life, this State has yet so successfully solved the problem of juvenile pauperism, that out of a population of two and a half millions it has only twenty-eight hundred and fifty-two wards to support. The State has a nursery at Roxbury, where destitute infants are cared for while requiring medical or surgical treatment, and where children boarded out are brought for treatment when necessary. The nursery is a temporary home only in the strictest sense of the word, boarding-out being the end in view. There is also a temporary boarding-place at Arlington with a capacity for only twenty children, and a home for wayward boys, with a capacity for seventeen. The State has two industrial schools, the Lyman school for boys and the State industrial school for girls, which together cared for three hundred and ninety-one boys and girls during the year 1896. There are also two reform schools, having three hundred and ninety-seven children in charge. With these exceptions the dependent children of Massachusetts are placed or boarded out."

Conan Doyle upon Enteric Fever among the British Troops in South Africa.—Conan Doyle, writing to the *British Medical Journal*, says: "The outbreak of enteric fever among the troops in South Africa was a calamity the magnitude of which had not been foreseen, and which even now is imperfectly appreciated. We naturally did not dwell too much upon it while the war was in progress, but it was appalling in its severity both in quantity and quality. I know of no instance of such an epidemic in modern warfare. I have not had access to any official figures, but I believe that in one month there were from ten thousand to twelve thousand men down with this most debilitating and lingering of continued fevers. I know that in one month six hundred men were laid in the Bloemfontein cemetery. A single day in this one town saw forty deaths. There is one mistake we have made which will not, I think, be repeated in any subsequent campaign. Inoculation for enteric fever was not made compulsory. If it had been so, I believe that we should (and what is more important, the army would) have escaped from most of its troubles. No doubt the matter will be

fully threshed out in statistics, but our strong impression from our own experience is that, although it is by no means an absolute preventive, it certainly modifies the course of the disease very materially. We have had no death yet (*absit omen*) from among the inoculated, and more than once we have diagnosed the inoculation from the temperature chart before being informed of it. Of our own personnel, only one inoculated man has had it, and his case was certainly modified very favorably by the inoculation."

The Female Army Nurses now number one hundred and forty-five, practically all of whom are either in the Philippines, stationed at the hospitals of the various garrisons throughout the archipelago, or on their way there.

A Natural History Note.—A physician of Dyersville, Iowa, now on his travels, writing to *The Commercial* of that place a description of an ocean trip, says: "We have met several ships and have seen lots of flying-fish, which are three to four feet long and longer. When they jump from the ocean, they look more like a hog than a fish."

Plague Infection by Fleas.—The danger of infection by fleas exists, to those near the sick, but this insect does not infest man in great numbers, and besides it can gorge itself with bacilli only in the last days of the disease, since until then these do not appear in the blood. The most frequent cases of contagion are those of physicians who have made post-mortem examinations, doubtless from coming in contact with the blood and with organs infected by the microbes. Two of Kitasato's assistants acquired the plague in Hong-Kong in this way.—Dr. Montenegro on Bubonic Plague.

A New Terror of Courtship has been developed in the case of an Indiana brunette. For some days she had been suffering from a supposed attack of pleurisy, but, when Dr. S. F. Bordman was called in, he found that one of the young lady's ribs was fractured. After much questioning, the girl blushingly admitted that her best beau had inflicted the injury while giving her his usual tender embrace before parting on his last visit. The occurrence of the accident was marked by a sharp pain in the side, "a catch in her breath," and a sudden relaxation of her hold.—*Chicago Medical Recorder*, July, 1900.

Power of the Eye.—"We often hear," writes Hiram M. Stanley, "people say that they can merely by a steady gaze affect a person at a distance, who is not looking at them, and some say that they are able to make one sitting in front turn the head in this way. Mr. Bell in his 'Tangweera' mentions this feeling when he says: 'Presently I felt as if some one was looking at me, and raising my head I saw a large puma standing ten yards away.' To the physiologist it may seem uncalled-for to investigate a manifest absurdity, but it has at least a practical value to explode a common error by direct experiment. I asked a young man, who is very confident of his powers, to stand unknown to reagent A behind a bookcase and look through a carefully concealed peep-hole. I gave him the best opportunity, placing A about four feet from the hole directly facing him, and I engaged A in mechanical writing. To the young man's confessed disgust and irritation he was unable to disturb A. My few experiments were negative in results. However, it may be that telepathic influence is exerted under certain conditions, and experiments with twins and others constantly *en rapport*, especially when under emotional stress and at critical junctures, might be worth trying. If there is nervous telepathy, this is perhaps as simple and common a form as any. If disturbance arose subconsciously the test would be that the tracings from an instrument, to show nervous conditions, should show large fluctuations coincidently with the times when the agent regards himself as successful."

The Heat in Paris.—The long uninterrupted spell of tropical heat, unprecedented in Paris during the present century, is producing most deplorable results. The list of persons who succumb in the streets is lengthening every day, and all the inhabitants and guests in the French capital are suffering real inconvenience from the high temperature. At the same time the water-supply is running short, and the ice manufacturers find it impossible to satisfy the demands of all their customers. There is, however, a yet more serious effect of the prolonged heat and drought. The water in the Seine is not only very low but has just below Paris become absolutely putrid. A few days ago all the fish in the river died, it was alleged from the heat of the water. Efforts were made to collect their dead bodies and to bury them; but they were so numerous that though they were carted away by wagon-loads those which remained floating on the water rendered life in the suburban villas almost impossible. Together with the sewage which flows into the Seine at St. Ouen these dead fish have transformed the Seine at Argenteuil, Bougival, Marly, Croissy, and Chalons into a veritable cloaca. The river inspectors have declared that nothing can be done to improve the situation but to wait patiently for a heavy fall of rain to raise the waters of the Seine and to increase the current which will carry away the putrid matter.—*Public Opinion.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 10, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Louisiana, New Orleans	July 28th to August 4th	4	1
Massachusetts, Lowell	July 28th to August 4th	5	
Nebraska, Omaha	July 28th to August 4th	1	
N. Hampshire, Manchester	July 28th to August 4th	2	
Ohio, Cincinnati	July 27th to August 3d	1	
Cleveland	July 28th to August 4th	6	1
Washington, Tacoma	July 21st to 28th	1	
Smallpox—Foreign.			
Belgium, Antwerp	July 7th to 21st	..	4
Egypt, Cairo	June 23d to 30th	..	1
England, London	July 7th to 21st	31	
France, Lyons	July 7th to 14th	..	1
Gibraltar	July 15th to 22d	1	
India, Bombay	July 3d to 10th	..	4
Calcutta	June 30th to July 7th	..	18
Karachi	July 1st to 8th	4	1
Madras	June 30th to July 6th	..	3
Mexico, Vera Cruz	July 21st to 28th	..	2
Russia, Moscow	July 7th to 14th	8	3
Odessa	July 7th to 21st	8	4
Warsaw	July 7th to 14th	..	6
Scotland, Glasgow	July 19th to 27th	48	2
Switzerland, Geneva	June 30th to July 7th	5

Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 58, No. 8. Whole No. 1555. NEW YORK, AUGUST 25, 1900. $5.00 Per Annum. Single Copies, 10c.

Original Articles.

ERRORS CAUSED BY THE FALSE INTERPRETATION OF THE ROENTGEN RAYS, AND THEIR MEDICO-LEGAL ASPECTS.[1]

BY CARL BECK, M.D.,

NEW YORK.

SINCE the Roentgen rays began their triumphant march from the modest town on the Main throughout the world, our knowledge of the obscurer ailments has been greatly enlarged, and our methods of treatment have been revolutionized. It may safely be said that treatises on fractures, for instance, which were written before the Roentgen era, have ceased to be regarded as authoritative. The proofs of the immense usefulness of the Roentgen rays in surgery are so overwhelming, indeed, that to discuss them would be carrying owls to Athens.

Unfortunately the strangeness of the subject soon attracted many imaginative and speculative minds, that drew unwarranted conclusions and spread erroneous impressions. The ease with which some of the small bones of the human body can be reproduced by the rays on a photographic plate led many medical novices and even ignorant laymen to the indiscriminate use, or rather abuse, of the new discovery. Little wonder that the consequences of such abuse of the rays were soon heralded and misapplied by officious friends, inconsiderate and malicious confrères, and last, but not least, by shyster lawyers. It naturally shared the fate of other inventions, as did anæsthesia and asepsis, and as still do many new remedial measures.

The public mind was deplorably disturbed by reports of extensive dermatitis and gangrene of the skin. But while in some individuals a peculiar trophoneurotic idiosyncrasy may exist, predisposing to dermatitis, in the great majority of cases the burns of the skin were caused either by the ignorance of the unskilful operator, the tube often being too near the object, or by too prolonged and too often repeated exposures. Such accidents are not surprising so long as laymen, such as opticians and instrument makers, who understand nothing of the anatomy and physiology of the skin, are intrusted with "the manufacture of skiagrams." As in many other respects, the question of "proper dosage" must also here be perfectly understood by the operator. A person who irradiates a patient suffering from sycosis, for instance, every day intensely for a whole hour, irrespective of the reaction following such a radical procedure, so that gangrene occurs, is as much qualified to do skiagraphic work as is a shoemaker to prescribe morphine.

Since February, 1896, I have made nearly three thousand skiagraphs, and have never observed the slightest irritation of the skin in any case in which the rays were used for diagnostic purposes. In but two cases did circumscribed depilation supervene. In both skiagraphy of the skull was required frequently and at short intervals. In the first case depilation began after the fifth, and in the second case after the sixth, exposure. Within three weeks the depilated spots had recovered their hair. In addition to such misadventures, crass ignorance is responsible for many distorted Roentgen-ray pictures, which caused such fatal errors that even medical men felt much discouraged by such results. But in considering these errors more closely, it becomes evident that the Roentgen rays never lie, but that it is entirely our own imperfections which induce us to err under peculiar circumstances.

In order to avoid errors, it should in the first place never be forgotten than a so-called Roentgen-ray picture is by no means an ordinary photograph of an object, but a silhouette only (skiagraph)—that is, a photograph of its shadow. To interpret such shadows properly, a thorough knowledge of the normal anatomical relations of the tissues, especially of the bones, that produce such shadows, is required. As the most minute gradation of density is registered, it is important to be thoroughly acquainted with the anatomical relations of the bones producing the doubtful shadow. The question, then, would be whether the supposed shadow is normal or not. On certain portions of the skeleton the muscles and tendons would naturally cause obscure shadows. The carpus is especially likely to produce such errors in the skiagraph; the tuberosities of the trapezium, the scaphoid, the hamulus ossis hamati, the os pisiforme, and the eminentiæ carpi volaris, radialis, and ulnaris double up the thickness of the carpus, thereby causing dark shadows, which might be mistaken for foreign bodies. Similar considerations and similar cautions apply to the other diagnostic opportunities offered by the rays.

If a skiagraph of the human hand, for instance, is taken, the plate will show the least light where the bones rest, while the soft tissues appear opaque. There is also a difference of opacity according to the thickness of the tissues, their blood-supply, and their air-capacity. The foot, while easily skiagraphed in the direction of the dorsum toward the planta pedis, from the toes up to the upper third of the metatarsus, presents an obstacle farther backward in the first and third cuneiform bones and the scaphoid, so that it is necessary also to skiagraph the foot on these portions transversely by having the outer face rest on the support. It is by this procedure only that the isolated shadows of the astragalus, the calcaneum, the os cuboidum, the scaphoid, and the fourth and fifth metatarsal bones can be distinctly outlined, so that false interpretations may be excluded. In the early era of the Roentgen rays the normal sesamoids were also sometimes incorrectly interpreted.

How important the knowledge of minute anatomical details is, especially of non-pathological abnormalities, will be evident from the fact that the os intermedium cruris (os trigonum tarsi) has been mistaken for a fragment severed from the astragalus. This bone is a typical part of the tarsus of all mammalia, and its frequency is estimated at from seven to eight per cent. Shepherd, who mistook this bone for a fractured fragment, says: "The fact that this fracture is not mentioned in any of the text-books of surgery or in special

[1] Read before the Society of Medical Jurisprudence of New York, May 4, 1900.

treatises on fractures would easily be accounted for by its only being discovered by dissection; it causes no deformity, and the symptoms it would give rise to during life would probably be obscure." The same author tried to produce this fracture artificially on

Fig. 1.—Os Trigonum Tarsi in a Man Forty Years Old.

the cadaver, but "in every case," he says, "where this manœuvre was performed, I failed, even when the greatest force was used, to break off the little process of bone mentioned above." Pfitzner regards the os trigonum tarsi as an integral part of the posterior process of the astragalus in the adult, which is analogous to the os intermedium antibrachii.

The practical significance of this bone is evident from a case described by Wilmans, which is also highly interesting from a medico-legal standpoint: A laborer claimed that he was injured by an iron bar on January 20, 1897, but was able to work during the whole day. On the following day he called on Dr. Wilmans, complaining of intense pain at his internal malleolus. He limped and asserted his inability to work. Wilmans found a slight swelling below the right internal malleolus. Ecchymosis of the skin being absent, the swelling was attributed to the presence of a considerable degree of talipes, from which the laborer suffered at the same time. The leg was elevated and fomentations were applied for several days. The patient still complaining of great pain, it was decided to transfer him to a hospital for observation. When discharged, after several weeks of treatment, the laborer made an effort to resume work, but at once declared that he was unable to keep it up. He was therefore admitted to another hospital, where he repeated this manœuvre several times during a period of six months. Finally he claimed damages for having been crippled by the injury sustained on January 20, 1897, but in view of the negative objective condition found by Dr. Wilmans, the society decided not to grant any claims. The consequence was that the man was transferred to the surgical division of a third hospital for further observation. There he complained that he had continuous pains below the right external malleolus, even while in the recumbent position. The pain increased during walking or sitting. Stepping on the right heel he also declared to be impossible. By distracting his attention, however, it was noticed that he could stand well on his heel, and he would undoubtedly have been declared a malingerer, had not the Roentgen rays come to his rescue, at least temporarily. A skiagraph showed a bone-fragment at the junction of the astragalus with the posterior surface of the calcaneum. On the strength of this skiagraphic "proof" Dr. Wilmans, although still mistrusting, was forced to modify his original opinion, and certified that the patient suffered from "fracture of the astragalus, in consequence of which he was damaged for life." The laborer therefore received an annuity of thirty per cent., in proportion to the estimated curtailing of his wages. Soon afterward the laborer was discovered by Dr. Wilmans carrying a heavy load without any apparent pain, while formerly he had claimed to be unable to walk without a cane or a crutch. Now Dr. Wilmans insisted upon a second irradiation, this time also skiagraphing the uninjured left foot. The skiagraph showed the "severed bone fragment," which had first been regarded as a sesamoid of the musculus flexor longus hallucis, but which was now recognized as a normal os intermedium cruris. The society of course refused the annuity, and the German supreme assurance court, to which the man had appealed, not only sustained the verdict of the society, but also decided that the laborer must return the annuity which he had unjustifiably enjoyed for eighteen months.

The practical significance of the os trigonum tarsi is also evident from the case of a laborer forty years of age, who reported to me that he broke his ankle by falling from a stairway. After four months' treatment in a mining district of Pennsylvania he still complained of considerable pain in the ankle, the intensity of which increased when he stepped on the foot. Limping was also present to a great extent. The protuberance of the left external malleolus and the well-marked tenderness at this region pointed to a fracture of the external malleolus, united in a deformed position. On the internal side but little swelling and considerable tenderness could be noted. A skiagraph, (Fig. 1) taken in the antero-posterior direction with a slight lateral turn, showed a dehiscence to the extent of ½ cm. on the external malleolar side. The gap was partially filled with callus. On the internal malleolar side the marked evidence of a separation of a small bone fragment could be seen, just as it is observed in Pott's fracture. It appeared to be displaced downward to the extent of ½ cm. and its upper surface looked so much like the lower surface of the internal malleolus, that it seemed to be almost certain that the two surfaces belonged to each other and had only recently been separated by external violence. Consequently I assumed that there was a typical case of Pott's fracture, and that the pain in the sphere of the internal malleolus was due to the pressure caused by the displaced fragment. While considering its removal, I studied a second skiagraph in the lateral position, and, to my great surprise, recognized the integrity of the internal malleolus. Now it became clear to me why there was no callus formation around the alleged bone fragment and why at the same time the connection with the astragalus was so close. By skiagraphing the healthy foot a normal os trigonum tarsi was found. This showed that the patient had sustained a fibular fracture only, which became united in a deformed position, and that the alleged fragment, which had misled me at the first exposure, represented the intact os trigonum tarsi.

The same considerations apply to normal muscular sesamoids, heretofore unrecognized. This I found a sesamoid, belonging to the semitendinosus muscle, in the popliteal space, in the same percentage (8).

The significance of a skiagraph for the purpose of estimating the degree of functional disability is not always conclusive. A skiagraph (Figs. 2 and 3) may show a considerable degree of bony deformity after a fracture, and still the function may hardly be disturbed at all. Skiagraphic test has shown that, as a whole, even our best functional results show by no means an ideal union. An unscrupulous patient who secures possession of a skiagraph of his own case, which shows considerable deformity, may, although there is no functional disturbance, strongly appeal to a jury on the strength of his skiagraph, if he succeeds in simulating great impairment. On the other hand, there may be but little evidence of bone injury on the skiagraph, but there may be severe impairment of function on account of the injury to the soft tissues (circulatory, trophic, or inflammatory disturbances), which can be represented only faintly, if at all. This shows the necessity of considering all the other clinical symptoms in connection with the skiagraph.

While it is easy, even for a layman, to understand the significance of most skiagraphs, there are, as alluded to, injuries the correct interpretation of which presupposes, besides thorough anatomical knowledge, the greatest care and a vast amount of experience as to the different modes of delineation in various projection planes. The greatest diagnostic difficulties are offered by the joints. The more complicated a joint is, the more complicated the skiagraphs of its various positions will naturally appear. It is especially the elbow joint and hip joint which are kept in view. First of all, the interpretation of the displacement caused by supracondylar fracture of the humerus, and the deformities resulting from it later on, may tax the power of discrimination considerably. The older the fracture, the less conspicuous the fracture line will appear, since it will be more or less overshadowed by the callus. In old fractures the lines cannot be represented as such, and it is only in case of union in a displaced position that its features can be guessed.

Fig. 2.—Vicious Union of Oblique Fracture of Femur, showing riding of divergent fragments, in a boy four years of age, seven weeks after the injury.

In the case of a lady aged seventy years, for instance, a second skiagraph, taken three years after a supramalleolar fracture was sustained, showed essentially the same features as the first, which had been taken four weeks after the injury.

In case of the entire absence of displacement it is only a very distinct skiagraph that shows the line clearly. It is natural that in such cases there is no skiagraphic evidence after recovery—that is, in from four to ten weeks, according to the type of the fracture. Should a court, for instance, doubt, in such an event, that there had been a fracture, a skiagraph taken after such a period might show a negative result, although there surely was a fracture. In this boy whom I present to you tonight, the very distinct skiagraph, taken only two months after he had sustained a subtrochanteric fracture of the thigh, showed no signs of a fracture. Had this case not been skiagraphed shortly after the injury, no evidence of the fracture could have been subsequently obtained. When no displacement existed, only a faint fracture-line will show, but the presence even of small amount of callus leaves no doubt as to the previous existence of a fracture.

Fig. 3.—Case Illustrated by Fig. 2, showing less deformity and loss of functional ability than should be guessed from the skiagraph.

On the other hand, callus formation may be so abundant that, in spite of the absence of displacement, the fullest evidence of fracture may still be furnished after months. In one of my cases, callus formation was so excessive that the attending physician was accused of malpractice, and it was the skiagram only which convinced the patient that his physician had treated him correctly, the bones being in perfect apposition, and which thus exonerated the practitioner.

The intra-articular fracture types offer the greatest diagnostic difficulties, inasmuch as the fracture line is also often obscured by the callus formation. If, however, a skiagraph of the other joint is made at the same time, in the same position, and in the same projection, the various delineations of the shadows will be correctly understood and interpreted.

A normal skeleton should also always be compared with the skiagraph. It should particularly be remembered that certain pathological conditions, such as rachitis, for instance, influence the outlines of the bones and may deceptively be supposed to represent a portion of an injury. In such an event the skiagram of the fellow-extremity will set matters right. In very young children the eminentia capitata appears as if entirely severed from the humerus, although the relations are absolutely normal. The explanation of this very important phenomenon is that the epiphyseal tissues are not sufficiently ossified to produce a shadow on the plate. If these points are not thoroughly considered, a displaced fracture fragment might be erroneously diagnosticated. Union between the epiphysis and the diaphysis of the head of the humerus is not perfect before the twentieth year. The lower epiphysis of the humerus consists of four nuclei, which ossify from the eighth to the seventeenth year.

The epiphyses of the trochlea as well as of the olecranon ossify between the seventh and twelfth years, which explains why an osseous nucleus that is still connected with its neighboring epiphyseal nuclei and the diaphysis by cartilaginous tissue appears as an isolated piece of bone which might erroneously be taken for a fragment. The acromio-clavicular junction sometimes shows in the skiagraph a hiatus of the width of a finger, so that a diastasis of the joint might be assumed. But since our knowledge on this new subject has increased, we know that this apparent diastasis is by no means pathological, and that there is a normal gap between the osseous ends of the acromion and the acromial end of the clavicle. The upper epiphysis and the diaphysis of the radius unite between the seventeenth and the eighteenth year, and its lower epiphysis and the diaphysis join in the twentieth year. During the early Roentgen era the translucent space above the epiphyseal cartilage in children was erroneously taken for a fracture line. The head of the femur unites with the diaphysis at the eighteenth or nineteenth year, and the lower epiphysis follows after the twentieth year. The upper epiphysis of the tibia unites with the diaphysis in the twentieth or twenty-second year, while the lower tibial epiphysis unites with the diaphysis between the eighteenth and the nineteenth year.

For the thorough interpretation of skiagraphs in children, it is important to know that at birth the diaphyses of the radius, the ulna, the metacarpal bones, and the phalanges are ossified, while their epiphyses, as well as the whole carpus, are still cartilaginous. It is not before the seventh year that an osseous nucleus shows at the lower epiphysis of the ulna. Union with the diaphysis sometimes begins with the twelfth year, but, as a rule, not before the fifteenth. Even then a small epiphyseal disc remains, which does not disappear before the seventeenth year in the female, and not before the nineteenth year in the male.

The osseous nuclei of the carpus show at different periods—viz., at the os capitatum at the fourth month; at the hamatum at the fifth month; while the triquetrum shows its nucleus between the second and the third year, the lunatum between the third and fifth, the naviculare between the fifth and the seventh, the trapezium and the trapezoid between the sixth and the seventh year, and the os pisiforme between the eleventh and the fifteenth year. After five years the capitatum, hamatum, and triquetrum have assumed their regular shapes, while the others, with the exception of the pisiforme, are perfectly developed at the twelfth year.

The osseous nuclei of the epiphyses of the metacarpal bones show at the second year, their synostosis with the diaphysis taking place between the twelfth and the seventeenth year in the female, and at the age of nineteen in the male. The epiphyseal nuclei of the phalanges are ossified between the fourth and the fifth year, their synostosis with the diaphysis taking place at the same age as that of the metacarpal bones (from the twelfth to the seventeenth year in the female, and between the sixteenth and the nineteenth year in the male).

Regarding the elbow-joint, it must be considered that an osseous nucleus appears at the medial side of the capitulum humeri between the second and the third year, another one in the internal epicondyle at the fifth year, a third in the trochlea between the eleventh and the twelfth year, and soon afterward a fourth in the external epicondyle. The nucleus of the internal epicondyle unites with the diaphysis between the sixteenth and the twentieth year; but the other three nuclei form a synostosis among themselves at the seventeenth year, and then form the uniform osseous epiphysis, which completes its synostosis with the diaphysis at about the twentieth year. In the capitulum radii an osseous nucleus appears between the fifth and seventh year, and in the olecranon between the sixth and the eighteenth year, both uniting with the diaphysis between the twentieth and the twenty-fifth, and between the sixteenth and the twentieth year.

Regarding the knee-joint it must be considered that the lower femoral epiphysis contains an osseous nucleus at birth, while the nucleus in the tibial epiphysis shows shortly afterward. At the fourth year both these epiphyses have completed their development, but they do not unite with the diaphysis before the fifteenth year. The anatomical text-books say that union takes place between the seventeenth and the twenty-fourth year, but skiagraphic experience points to an average period of only sixteen. The osseous epiphyseal nucleus of the fibula appears beween the second and the fifth year, and unites with the diaphysis between the eighteenth and the twenty-fifth year; but skiagraphy dates this period earlier, viz., the fifteenth year. The osseous nucleus in the tibial spine appears between the eighth and the tenth year; the epiphyseal line between it and the diaphysis disappears at the fifteenth year.

As to the bones of the foot, it may be said that the lower epiphyses of the tibia and fibula show their osseous nuclei in the first and second years, and unite with the diaphysis between the eighteenth and the twenty-fifth year; according to skiagraphs, as early as before the eighteenth year. The osseous nucleus of the astragalus and calcaneum appears in utero, that of the cuboid shortly before or after birth, that of the cuneiform bones between the first and the fifth year, and that of the os naviculare from the first to the fifth year. The osseous nuclei of the metatarsal bones and of the phalanges appear from the second to the tenth year, and unite with the diaphyses between the sixteenth and the twenty-second year.

In elbow-joint fractures occurring in childhood it is necessary, therefore, to take at least two skiagraphs in different projection planes and to compare them thoroughly with the normal fellow. In a case of fracture of the femoral head, for instance, the deformity had appeared three times as large as it actually was, on account of inappropriate projection. The degree of shortening of the limb was overestimated accordingly. This shows the necessity of considering the other clinical symptoms and data in connection with the skiagraph.

In fractures of childhood it should also be remembered that the process of ossification is influenced by various affections of the bone, as, for instance, by rickets.

How important the question of projection is becomes evident when we consider that grave errors may sometimes occur even if all the preliminary conditions required for a thorough understanding of the case seem to be fulfilled. This will appear from the following experience, which has probably not been paralleled in the literature of this subject (compare *New York Medical Journal*, January 6, 1900).

A boy four years of age, while playing in the street, fell against an iron bar. Being unable to rise again, he was taken up and carried to St. Mark's Hospital, where in the first instance moderate pain was noted besides the functional disturbance. There was neither any difference in level or any other deformity, nor any shortening or the typical equinus position. A photograph taken two days after the injury only showed a very moderate and uniform swelling of the leg. Abnormal mobility and crepitus, in accordance, could be produced only by very rough manipulations.

On the day following the injury two skiagraphs were made in different positions; one of them in the dorsal and the other in the lateral position. To my

surprise, the one which had been skiagraphed by a direct irradiation, the centre of the platinum disc of the tube being perpendicular to the anterior surface of the leg, did not show the slightest indication of a fracture, while the one which represented the leg irradiated from the outer aspect of the tibia showed a marked fracture line. The fracture presented the typical oblique type in the middle of the tibia, the fracture line running from below anteriorly to above posteriorly, the upper, tapering fragment overlapping the lower end. No sideward displacement having been present, it can be understood why the rays reaching the long axis of the tibia in a vertical direction did not show the fracture line. A very slight change in position, when the inclination toward the fibular direction amounted to less than 1 mm., brought out the fracture distinctly.

Now if I had, as is the custom in general, taken a skiagraph in the antero-posterior direction only, and if the manipulations made during the first examination were carried out as gently as they properly should be, the fracture might have been overlooked entirely. And if, in view of the local pain and tenderness, the swelling, and the functional disturbance, the possibility of a fracture had been seriously considered, the skiagraph might have silenced the uneasy conscience.

If the case had been brought before a jury, the expert might there on the strength of the first skiagraph have testified in good faith that there was no fracture.

This experience teaches the necessity of adopting the principle of always taking at least two skiagraphs in two different positions in all cases of suspected fracture.

In taking skiagraphs of foreign bodies it must be considered that their size varies according to the distance from the tube. In oblong bodies great errors as to their extent may be committed. Once I was very much surprised in a case in which a needle-fragment had entered the palm of the hand in a perpendicular direction. The plate, while indicating the presence of the needle, distinctly created the impression that the fragment was only about 2 mm. in length. When extracted it was found to be more than an inch long, the rays having reached the hand in a perpendicular direction so that the circumference of the fragment was reproduced rather than its length. A side view, of course, would have cleared up the error at once.

Misinterpretations have also arisen from unavoidable mechanical and chemical defects, causing markings in the photographic plate, the significance of which must be well known to the skiagraphic interpreter. Blemishes may also be produced by spots caused by pus from wounds or by perspiration.

In the location of foreign bodies, especially in the skull, many errors were and are still committed. Their avoidance will be considered in a special article.

The case of the German malingerer is a striking illustration of the significance of the Roentgen rays, which for a time proved a protection on account of erroneous interpretation, but showed the case in its true light when assisted by better anatomical knowledge. Soon after the discovery of the Roentgen rays the courts were in a position to grant damages to patients, especially veteran soldiers, who claimed to have been damaged by bullets and were unjustly rejected by medical experts as malingerers. The presence of the bullet, shown on the photographic plate, cannot be denied, and a patient who harbors a piece of cold metal in any part of his body has, as a rule, a good reason to complain. On the other hand, an impostor, who pretends to have been shot and simulates functional disability, will be exposed by a distinct skiagraph, which would show the absence of the alleged bullet.

It is a question to be solved by my colleagues of the other faculty, whether the court has a right to censure a surgeon for not having used the Roentgen rays in a suitable case, and furthermore whether it can compel a patient in a doubtful bullet—or fracture—case to submit to an exposure to the rays.

A distinct skiagraphic plate will always tell the truth. If accompanied by the registration of the details of operation, viz., the source of the current (whether battery, static machine, or street), the length of spark of the induction coil, the intensity of the tube, the distance of the platinum disc of the tube from the photographic plate, the position of the object, the kind of plates, and the time of exposure, it will be a valid document, intelligible to every expert. And together with the anatomical and clinical knowledge of the expert it should be evidence in court.

THE PRESENCE OF VIRULENT TUBERCLE BACILLI IN THE HEALTHY NASAL CAVITY OF HEALTHY PERSONS.

By NOBLE W. JONES, M.D.,

CHICAGO, ILL.

(FROM THE PATHOLOGICAL LABORATORY OF RUSH MEDICAL COLLEGE, CHICAGO.)

It cannot at present be stated that the methods of infection of tuberculosis are well understood. Since the discovery of the bacillus tuberculosis in 1882 much work of a various nature has been done to throw light upon this important subject. Some of this has been most thorough and painstaking; much, on the other hand, has been of a purely miscellaneous character. Assuming the purely parasitic nature of the tubercle bacillus, this work has naturally tended toward the study of the micro-organism in its relation to the bodies and excretions of animals affected with tuberculosis, and the atmosphere and the dusts which have been supposed to contain portions of these materials as component parts. The former belief of a universal atmospheric contamination was first disproved by the work of Cornet, who has shown that virulent tubercle bacilli are not to be found in atmospheres unfrequented by consumptives. This has since been verified by the works of many other investigators. The question of the infectiousness of dust, on the other hand, is far more important in that all recent researches show more or less causative relations existing between infected dust and the various forms of the disease, particularly inhalation tuberculosis.

Briefly reviewing some of the literature bearing on this subject, it is to be noted that Klebs[2] does not believe infected dust to be a potent factor in the causation of the pulmonary disease. Cornet[1] agrees that the dust of the street is not of much importance in its production, because, as he has shown, the bacillus loses its virulence within a few hours under the action of the direct rays of the sun, although Marpmann[3] claims to have found virulent bacilli in this material. Indeed, Heron and Chaplin,[4] of London, state that dust that has come in contact with the excreta of tuberculous patients does not play a very important rôle in the carrying of this infectious germ. Their series of one hundred inoculation tests with guinea-pigs, using dust collected from six important hospital rooms, including wards, laboratory, waiting-rooms, etc., show but two dead of tuberculosis. The clinical statistics of the London hospitals during a period of twenty years prior to 1894, as summarized by Theodore Williams,[5] also seem to point to a like conclusion. On the other hand, the more recent work of Cornet[1] in Berlin shows positively, he believes, that the factor of infected dust is an important and dangerous one, especially to those in attendance upon tuberculous pa-

tients. The source of greatest infection, according to his work, is tuberculous sputum that has become dry. The mucous contents of the nasal cavities is less infectious for obvious reasons. The spread of tubercle bacilli through the urine, the fæces, or tuberculous pus is of but slight importance, because, first, they are present in small numbers only; secondly, they die on decomposition of these substances. And, finally, the expired air from the patient, when not laden with fine droplets of mucus and saliva thrown out by coughing, speaking, or forced breathing, contains no tubercle bacilli whatever, as has also been demonstrated by numerous observers, namely, Buchner, Weinich, F. Müller, Straus,[6] etc. In all, Cornet collected one hundred and forty-nine samples of dust from various places frequented by tuberculous patients, namely, hospitals, insane and orphan asylums, prisons, private rooms in which such patients lived, surgical wards, streets, etc., and made inoculations into three hundred and ninety-two animals. Fifty-nine animals became tuberculous, representing forty samples of the dust, or a percentage of 26.8. On the other hand, twenty-nine animals inoculated with dust from non-infected places remained healthy.

An interesting series of experiments has recently been made by R. Sticker,[7] under the direction of Flügge, in Breslau, with the direct object in view of showing the infectiousness of dust bearing dry powdered sputum. In the first place, three attempts were made by blowing fine, sterile dust into the faces of guinea-pigs, and with negative results. He then treated twenty-nine guinea-pigs in a similar manner with infected dust. Of the first eleven experiments in which comparatively strong currents of air were used—*i.e.*, a rate of one metre per second—seven gave positive results. Of the succeeding eighteen experiments with weaker currents of air none resulted positively, that is, in producing inhalation tuberculosis, but in the latter case he was able to obtain bacilli on receptive plates (*Vorlagen*). He concludes that virulent tubercle bacilli can be disseminated in dust under the influence of strong currents of air, as above indicated, and also that highly dried sputum, under the influence of weaker currents, can carry bacilli when mixed with the finest, lightest dust; but the number is dependent (*a*) upon the strength of the air stream, and (*b*) upon the absence of moisture. Such conditions must necessarily more or less limit the operation of this factor in general infection, for, as Flügge[8] well says, such conditions cannot be applied to the conditions actually surrounding persons. Again, the danger of the use of handkerchiefs by phthisical patients, and the dissemination of tubercle bacilli in dust therewith, are referred to by Cornet,[1] Laschtschenko,[9] and Beninde.[10] The latter has shown experimentally that particles of mucus laden with bacilli can be blown from wet handkerchiefs by strong currents of air, while weaker currents are entirely unable to do this. On the other hand, when the handkerchief is dry, weaker currents are also able to disseminate bacilli. But Flügge,[5] again, maintains that practically such a condition of dryness is never obtained, and, although agreeing with Cornet that such a condition is possible, he believes it to be a doubtful factor.

There is not, to the same degree, this uncertainty surrounding the experiments with coughed, sneezed, or sprayed sputum that one notes in the case of dust experiments. Quite all writers are agreed that fine droplets of mucus laden with tubercle bacilli have been shown experimentally to play an important rôle in the dissemination of this microorganism. In recent years great stress has been laid upon this factor by Flügge and his pupils. Laschtschenko[9] has shown that on moderate speaking, sneezing, and coughing, growths could be obtained on agar plates when the mouth had been washed with a solution containing Bacillus prodigiosus. Not so, however, in the case of ordinary breathing. Out of nine attempts with phthisical patients, four guinea-pig inoculations resulted positively, and of a second series three experiments gave two positive results. In these experiments the patients, washed and dressed in sterilized clothing, were placed in a glass cage, which previously had been disinfected, and were allowed to remain in it for some time in order that mucous droplets thrown out on coughing, speaking, etc., might fall into dishes containing sterilized salt solution, which in turn was used for the inoculation. Heymann[11] has in a somewhat different manner obtained the same results. He caused phthisical patients to cough through a tube into a sterile box containing guinea-pigs, and out of six series of experiments in which were used twenty-eight animals, six became tuberculous, representing four of the series. Similar results have been obtained by von Esmarch,[12] Hübner,[13] and V. Weissmayr.[14]

In all cases the elements of distance and duration of exposure play most important parts. Heymann shows that at a distance of 50 cm. there is marked distribution of bacilli on the slides; that this continually decreases up to a distance of 1.5 metres, when the slides remain free, and also that it is necessary to collect 10 cubic metres of air at this distance to obtain occasional positive results. It is quite apparent that such experiments as these teach us certain limitations of the infectiousness of tuberculosis by these methods of dissemination also. It is quite true that many phthisical patients probably do not distribute bacilli at all, or again only at certain periods of the day, or at certain stages of their disease, so that it is reasonable to believe that the thorough employment, on the part of the patient himself, of the ordinary prophylactic measures now used in hospitals would restrict enormously the spread of the disease. Flügge concludes a review of the present status of our knowledge of tuberculous infection by stating that infection will result, first, in those places in which tuberculous sputum has been allowed to dry on the floor and fixtures, and in which the air is filled with a visibly coarse dust; such dust being scattered by the walking about of persons, the continuous vibration of machinery, railroad coaches, etc. But even under these conditions the probability of infection is brought about only by a person's remaining in such places continuously for a relatively long time. Secondly, concerning the spread of bacilli through fine droplets of mucus, infection is practically possible only when repeated approximation to coughing patients takes place within a distance of one metre, such as may occur in the case of nurses, or occupants of factories, counting-rooms, wórkshops, and the like, where the workers are closely crowded; and this danger, Flügge believes, could well be obviated by the use of proper prophylactic measures.

In 1894 Straus,[15] of Paris, proved that the presence of virulent tubercle bacilli could be demonstrated in the nasal cavities of those who, being non-tuberculous themselves, were in more or less constant attendance upon tuberculous patients. His experiments numbered twenty-nine in all, and were made upon hospital attendants, internes, and patients suffering with chronic maladies other than tuberculosis. The dirt, solid particles, and mucous contents of the nasal cavities were removed by sterile cotton swabs, washed into sterile bouillon or water, and the total solution was injected intraperitoneally into guinea-pigs by means of a large hypodermic syringe or small trocar. The result of this series of experiments was as follows: Seven animals died within a few days of septicæmia, or acute peritonitis; nine animals died, in times varying from twelve to thirty-three days, of tuberculosis of the omentum, mesenteric glands, spleen, and occasionally

the lungs and liver. The remaining thirteen animals were killed or died from causes non-tuberculous, after having lived a sufficient length of time for tuberculous lesions to have developed if bacilli had been introduced. In four of the nine animals showing positive results there were found caseous abscesses in the abdominal wall at the point of inoculation. These tests show the presence of bacilli in the enormous number of 40.9 per cent. of all persons experimented upon, the seven animals dead of septicæmia and peritonitis having been deducted from the total number because of their early deaths.

In view of what has been previously related, the questions naturally arise: (1) Are tubercle bacilli to be found in the nasal cavities of healthy individuals following the ordinary vocations of life? (2) Are they to be found in such proportions as Straus' work would show in the case of those in more or less intimate relations with the tuberculous; and if not in such proportions, in what numbers can we expect them to be present, bearing in mind the variations which different conditions and modes of life would necessarily produce? As tending to answer these questions, I wish to narrate the results of the following experiments. My object was to demonstrate, if possible, virulent tubercle bacilli in the nasal cavities of those who were free from tuberculous processes, and were subjected only to the ordinary amount of infection to which every dweller in a large city must submit. I failed in the effort to study public-school children as I had desired, and, therefore, relied upon my fellow-students to furnish me with this material. I am quite aware that an objection may here be raised concerning the environment of such persons. This was met as best it might, by choosing mostly men who were in good physical health, and who were not haunters of laboratories or clinics. The technic of the experiments was as follows: The entire contents of the nasal cavities, particles of dirt, of crusts, and of mucus were removed by five or six sterilized cotton swabs, made by spinning cotton on wires of suitable length, by carrying them back as near the pharynx as possible and cleansing the cavities from within outward. The nose and face were not previously washed or prepared in any way. These swabs were washed in test-tubes containing 10 c.c. of sterilized normal salt solution, by rotating them rapidly in the solution. The animals were then prepared in the usual manner. The hair covering the lower abdomen was removed by shaving and by a depilatory, and the surface scrubbed with soap and water and again with a ten-per-cent. formalin solution. The skin, fascia, and muscles were then nicked with sterile scissors, and the solution with its solid contents, measuring 5 c.c. or 6 c.c. in amount, was introduced into the peritoneal cavity by quickly plunging the point of a large glass capillary tube containing it through the remaining fascia and peritoneum. The wound then was closed by collodion dressings. Thirty-one inoculations were made, and briefly the results are tabulated below.

Experiment Number.	Date of Inoculation.	Number of days Lived.	Anatomical Diagnosis.	Bacteriological Examination.
I	Nov. 1, 1899.	73	Lobular pneumonia of both lungs; acute infectious changes of all visceral organs.	Negative.
II	do.	86	do.	do.
III	Nov. 3, 1899.	70	Double lobar pneumonia; infectious changes as above.	do.
IV.	do.	72	Lobular pneumonia and hypostatic congestion of both lungs; acute visceral changes as above.	do.
V	do.	70	Lobular pneumonia and acute visceral changes as above.	do.
VI.	Nov. 7, 1899.	59	do.	do.
VII.	do.	70	do.	do.
VIII	Nov. 9, 1899.	59	Tuberculosis of omentum and spleen; passive congestion of lungs, liver, spleen, and kidneys.	Staphylococcus aureus from omentum. Micrococcus tetragenus from liver and lungs.
IX.	Nov. 11, 1899.	78	Lobular congestion of lungs; the usual acute changes of visceral organs.	Negative.
X	do.	47	Multiple small abscess formations of spleen; acute infectious lesions of lungs, liver, and kidneys.	Staphylococcus aureus from spleen.
XI	Nov. 13, 1899.	79	Lobular pneumonia and the usual visceral changes.	Negative.
XII.	Nov. 16, 1899.	73	do.	do.
XIII.	do.	65	do.	do.
XIV.	do.	65	do.	do.
XV.	Nov. 25, 1899.	8	Tuberculosis of omentum; lobular congestion and emphysema of both lungs.	Micrococcus tetragenus from heart's blood.
XV.a.	Dec. 2, 1899.	26	Tuberculosis of spleen; miliary tuberculosis of liver and lungs.	Negative.
XVI	Nov. 25, 1899.	14	Lobular congestion and emphysema of both lungs; passive congestion of liver, spleen, and kidneys.	do.
XVII.	do.	43	Lobular congestion of both lungs; the usual acute infectious changes of visceral organs.	do.
XVIII.	do.	49	Abscess formation of spleen; metastatic abscesses of lungs and liver.	Staphylococcus aureus from spleen; Micrococcus tetragenus from kidneys.
XIX.	do.	73	Lobular pneumonia of both lungs, and the usual visceral changes.	Negative.
XX.	Dec. 6, 1899.	33	Lobular and hypostatic congestion of both lungs, and the usual visceral lesions.	do.
XXI.	do.	15½	Abscess formations of rectus abdominis muscle; metastatic abscesses of liver; the usual inflammatory changes of visceral organs.	Staphylococcus aureus from rectus abscess.
XXII.	do.	14	Tuberculosis and abscess formations of spleen; miliary tuberculosis and metastatic abscesses of liver and lungs; passive congestion of kidneys, lungs, and liver.	Staphylococcus aureus from spleen; Bacillus coli communis from spleen and liver.
XXIII.	do.	20	Lobular congestion of both lungs, and the usual visceral lesions.	Negative.
XXIV.	Feb. 22, 1900.	18 hrs	Acute septicæmia.....	Streptococcus pyogenes from intraperitoneal fluid.
XXV	do.	17	Passive congestion and hemorrhagic infarction of lungs.	Negative.
XXVI.	do.	20	Lobular congestion of lungs and passive congestion of spleen, liver, and kidneys.	do.
XXVII.	do.	13	do.	do.
XXVIII.	do.	3	Diffuse purulent peritonitis.	Staphylococcus aureus from intraperitoneal fluid.
XXIX.	do.	20	Lobular congestion of lungs; passive congestion of liver, spleen, aod kidneys.	Negative.
XXX.	do.	17	Lobular congestion of lungs; anæmic infarction of kidneys; marked gastrectasis; passive congestion of liver.	do.
XXXI.	do.	19	Lobular congestion of lungs; passive congestion of liver and kidneys.	do.

It is desirable to describe somewhat in detail the tuberculous cases.

Case VIII.—The nasal contents of No. 8, a merchant by occupation, forty years of age, was inoculated into a guinea-pig intraperitoneally November 9, 1899. The animal died fifty-nine days later, and on post-mortem examination showed the following: The animal was large and well nourished; wound had healed by primary union. The omentum showed a large caseated mass on the external surface; the lungs, liver, and kidneys showed no visible tuberculous lesions. From the omentum the staphylococcus aureus was obtained by smears and cultures, and the micrococcus tetragenus from the liver and lungs. Cultivations from the spleen remained negative. Histologically the omental mass revealed tubercle formations with typical giant cells. There were congestion and diffuse miliary tuberculosis of the spleen. No tuberculous lesions were found in the liver, lungs, or kidneys.

Case XV.—A guinea-pig was inoculated November 25, 1899, intraperitoneally with the nasal contents from No. 15, a student twenty-seven years of age. The animal died eight days later. On examination the wound was found apparently healed by primary union. Six to eight small yellowish masses were found on the omentum underneath the cardiac end of the stomach. There were no mesenteric adhesions. The lungs, liver, spleen, and kidneys were free from visible lesions. The lungs, however, showed areas of lobular congestion and emphysema. Cultures and smears from the yellowish tuberculous masses remained negative. The micrococcus tetragenus was isolated from the heart's blood. Histologically the omental tubercles showed an aggregation of lymphoid cells with areas of necrosis near one surface. The remaining organs appeared as above described.

Case XVa.—A control animal was inoculated December 2, 1899, subcutaneously in the groin with three of the yellowish masses found on the omentum of Case XV. The animal lived twenty-six days, when it died in an emaciated condition. On post-mortem examination the wound was found to be healed by primary union. There was no swelling of the inguinal lymph glands. The omentum and mesenteric glands were free from change. The spleen was enlarged and congested; it contained several large caseous masses, the largest being the size of a bean. No further tuberculous lesions were found. Smears and cultures from the spleen resulted negatively. A bacteriological examination of the remaining organs was not made. Histologically tubercle formations were demonstrated in the spleen, but they contained no typical giant cells. A miliary tuberculosis of the liver and lungs was present.

Case XXII.—A guinea-pig was inoculated in a similar manner December 6, 1899, with the nasal contents from No. 22, a student aged twenty-six years, and died fourteen days later greatly emaciated. Post-mortem examination showed the wound to have healed by primary union. The omentum possessed several yellowish punctate bodies; as also did the under surface of the left lobe of the liver. The mesenteric glands were not swollen. The spleen was large, congested, and filled with large, yellow, caseated masses. The liver, lungs, and kidneys showed the usual acute infectious changes. Bacteriologically the staphylococcus aureus was obtained from the caseous masses of the spleen, and the colon bacillus from the tissues of the spleen and liver. The omental nodules appeared histologically as lymphoid tissue which had undergone partial necrosis. There were typical tubercle formations with giant cells and also local abscess formation in the spleen and metastatic abscesses of the liver and lungs.

The following cases are also of interest: Cases XXVI., XXVII., XXIX., and XXXI. These animals were inoculated February 22, 1900, as usual with the nasal contents from students. The animals lived from thirteen to twenty days, and on examination practically the same conditions were found in each, so that a description of Case XXVI. will suffice for all. The animal died after twenty days. It had lost some weight. The inoculation wound had healed by primary union. On the omentum were found two opaque grayish bodies, the size of half a split pea. The mesenteric glands were swollen and of the same color. The spleen, liver, and kidneys showed marked passive congestion, and the lungs lobular areas of congestion. Smears and cultures of the swollen glands remained negative, as also did the lung cultivations. Histologically, the omental and mesenteric glands showed a hyperplasia and partial necrosis of lymphoid cells. There were no unequivocally tuberculous lesions anywhere. The remaining visceral organs revealed the usual acute infectious changes.

Briefly summarizing the records, we note the following facts: Of the thirty-one animals inoculated, one died within a few hours of septicæmia, and another in three days of acute peritonitis; twenty-two died from acute pulmonic lesions of unknown origin, as all attempts to isolate micro-organisms from the lungs resulted negatively; and it is significant that nearly all of these deaths occurred during the extreme cold nights of the past winter months. The swollen mesenteric glands found in Cases XXVI., XXVII., XXIX., and XXXI. of this group are to be explained by the acute infection, as neither lesions resembling tuberculosis were found, nor was the presence of bacilli in the tissues demonstrated. Three animals died of staphylococcus aureus infection with multiple abscess formation of the spleen and liver after several weeks. One animal (No. XXV.) was drowned on the seventeenth day, and three died of or with tuberculosis in fourteen, twenty-six, and fifty-nine days respectively. The lesions found in these last cases are from a histological standpoint positively tuberculous. In Case XV., this was further proven by re-inoculation of the omental tubercles into another animal with resulting tuberculous lesions of the spleen. Very many most careful attempts were made to obtain the bacilli in the tissues, without success, but because of the technical difficulties so frequently encountered in finding them in tuberculous tissues in general, and in view of the positive histological and re-inoculation findings cited above, I do not hesitate to give these as positive results, making it possible to state that in this series of experiments three out of twenty-nine cases developed tuberculosis, or a percentage of 10.3.

It is to be noted that Flügge's conditions necessary for infection are not to be applied to these cases. In the case of No. VIII., a dealer in second-hand furniture, the physical examination showed him to be free from visible tuberculosis. He is not subject to the continuous breathing of visible dust, nor does he associate with tuberculous patients. The other two cases, those of students, are likewise not subject to these conditions, though, no doubt, from the nature of their work they are somewhat more prone to infection than the average person. In order to explain these findings we must, I believe, accept a wider range of possible infection than the experimental researches of Flügge and his *confrères* would allow, and, to my mind, the conclusions of Cornet as to the general infectiousness of contaminated dust satisfy these conditions in a more liberal way.

On taking up this work it was my intention to make further researches than I have recorded, but circumstances prevent it. I believe the question justifies further observations—observations which should be exhaustive and differentiative. It would be interesting, for instance, to determine whether or not the bacillus is limited to the purely respiratory portion of the nasal cavities. Its occurrence on the pharyngeal mucous membrane, in the lacrymal secretions, in the external auditory passages, etc., should be studied. These are all matters that have some bearing upon the spread of tuberculosis.

In general we may conclude as follows: First, that virulent tubercle bacilli are to be found in the nasal cavities of healthy persons in the ordinary walks of life, as nearly as this series will represent this class; and, secondly, they are not to be found so frequently in these persons as in those who have the care of the tuberculous.

I wish to express my thanks to Dr. Ludvig Hektoen for advice and aid, and to Dr. T. R. Crowder for examining physically a number of the persons.

ANURIA FOLLOWED BY RETENTION OF URINE IN A CASE OF HYSTERIA.

By ALFRED GORDON, M.D.,

PHILADELPHIA, PA.,

ASSISTANT IN THE NEUROLOGICAL DEPARTMENT, JEFFERSON COLLEGE HOSPITAL.

Mrs. S——, forty-five years of age, had eight children, four living. At the age of thirty-five she had typhoid fever, and since, she says, she has not been feeling very strong. Her menses were regular, every twenty-eight days. Her present trouble began ten days after her married daughter was taken ill with scarlet fever; two days later her daughter's children took scarlet fever. Immediately previous to her daughter's illness her son underwent an operation for appendicitis. The patient, being very much attached to her family, became so much alarmed and affected, that a few days following her grandchildren's illness she developed the symptoms of anuria. When I first saw her, she affirmed that she passed a teaspoonful of urine in twenty-four hours. After questioning her again and again, she repeatedly assured me of the truthfulness of her assertion. I immediately catheterized her, but could obtain only a few drops of urine. Palpation and percussion of the region of the bladder did not reveal any dulness. The patient seemed to be perfectly normal. There was no complaint of headache or of pain in any part of the body. She passed a comfortable night. On the following day, not having passed urine she became alarmed. One of her daughters told me that her mother constantly kept on talking of her condition and spoke even to neighbors of it. She had constantly in her mind the idea that she could not live without urinating, and that her kidneys were undoubtedly affected.

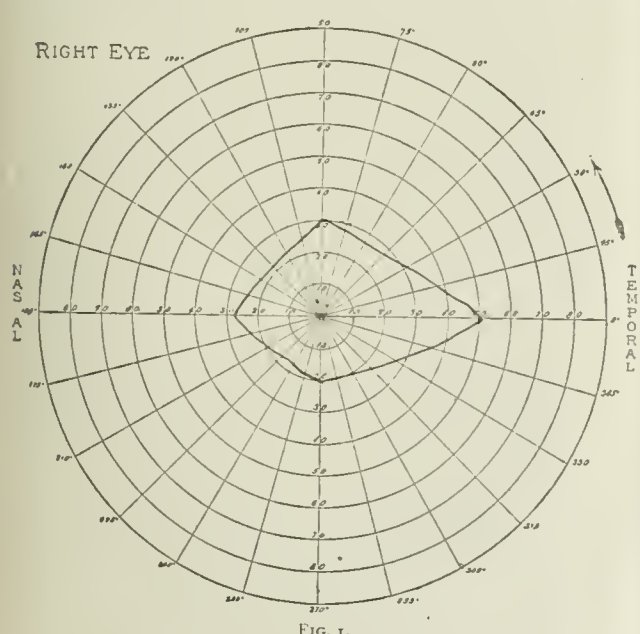

Fig. 1.

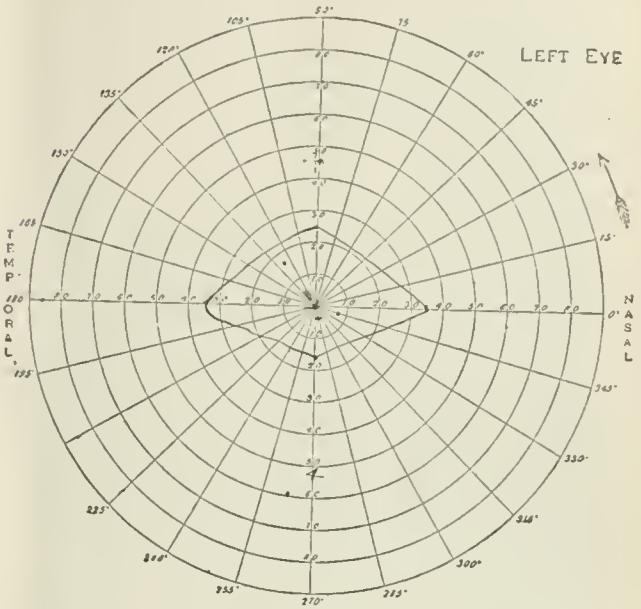

Fig. 2.

Knowing the family for a considerable length of time, I was aware of the fact that all the members of it were neurasthenic. The treatment on the first day consisted of abundant drinks, especially milk, hot applications to the region of the kidneys, and strychnine. At my third visit I was informed that the patient passed about two teaspoonfuls of urine, and with another catheterization I obtained again a teaspoonful of urine. What appeared to me remarkable, was that there was no vomiting, and the patient had no headache and apparently no suffering. The lumbar region was not sensitive; the abdomen was soft; the patient's bowels moved as usual, and in spite of two quarts of milk and two glasses of water a day she did not urinate. The only inconvenience the patient experienced was a perspiration during one night, and she affirmed that it had the odor of urine. She became very much alarmed and begged me to save her, as she expressed herself, because she was told by a friend she would not be able to urinate by herself, but she must ask her doctor to make her do so.

After excluding all possibilities of anything organic which could interfere with the function of the kidneys, and being somewhat struck by the comparatively non-suffering appearance of the patient, I began immediately an investigation in regard to hysterical symptoms. Of all stigmata that we usually find in hysteria there were only two: complete anæsthesia of the plantar region of the right foot, and a very marked concentric narrowness of the visual field in both eyes (Figs. 1 and 2). While the normal field of vision is 95° for temporal region, 55° nasal, 65° lower, and 55° upper, in this case, as is seen by the charts, it was far below normal. These were the only symptoms of hysterical character which I found in my patient.

I have always been of the opinion that it is an error to think that only cases of true insanity are accompanied by physical stigmata of degeneration. I firmly believe that physical stigmata of degeneration lead very frequently to psychical degeneration, and not only in serious organic psychoses, but also in many functional neuroses, such as hysteria, epilepsy, chorea, neurasthenia. A person affected with any of these neuroses should always be watched closely, for al-

though of slight character, they might some day turn into a serious psychosis. I scarcely ever fail to detect more or less physical signs of degeneration in cases of chorea, neurasthenia, and hysteria, whether it is of the head, face, palate, hands, or feet. The early recognition of physical and psychical stigmata of degeneracy is of the highest importance in diagnosis. In examining any case of nervous disorder I make it a rule to look invariably for stigmata of this character, for their nature is of great value as to the future of the patient.

In the present case I could detect the following signs of degeneracy: ogival, deep palatine vault, one ear larger than the other, the second being almost perpendicular to the head; three bony elevations on the head, which was of square shape; a vestige of a supernumerary finger on the left hand. The deeper I went into my investigation the clearer appeared to me the cause of my patient's anuria. I was therefore convinced that I had to deal with a degenerate, who subsequent to an emotion due to diseases in the family to which she was so much attached, developed anuria. This anuria was not originated by any lesion bearing upon the functions of the kidneys, but was one of the symptoms of hysteria. My presumption was completely verified by subsequent events in the course of the disease.

I persuaded the patient that she was really ill (any other course would never make her believe me); that the trouble was in her kidneys, and that a special external application over the region of the kidneys would undoubtedly cure her. She was enchanted with my announcement, which I made most emphatically. Accordingly I prescribed a lotion composed of chloroform and alcohol, and advised her to rub it over the lumbar region for one minute every three hours. I told the patient to be as quiet as possible, this being a necessary element of the treatment; to carry out my instructions, and she would positively urinate the following day. My next visit was exactly twenty-four hours after the previous one. The patient and her daughter met me with a happy smile, and appeared to be glad to see me. To my satisfaction I learned that my instructions had been followed to the letter, and she had urinated a little more than a pint. She was very much encouraged, felt contented, and with a reaffirmation on my part felt sure she was recovering. This time again I told the patient that to-morrow she would urinate just as much as anybody else, and she would not have any more trouble. This suggestion worked remarkably well. Early on the following day the patient sent me word not to come, as she was entirely well; she urinated five times during the day and three times during the night; she began to eat full meals, and felt happy.

Four days later I was called in haste to see my patient again. I learned that she suffered intense pain in the lower part of the abdomen, and had not urinated for ten hours, but felt the desire to do so and could not. On uncovering the patient I found a swelling above the pubis which was evidently the distended bladder. Immediate catheterization brought a large amount of urine of very strong ammoniacal odor. The patient informed me that she rubbed over the abdomen the same lotion I prescribed for her previous anuria, but it did not give her any relief. I stated then that the lotion was a special remedy for the kidneys, but this retention of urine was due to some disturbance of the bladder, and I could cure this disease with another lotion specially for this case, but I preferred to wait until evening. In the evening I called again and found exactly what I expected. The patient had not urinated since the catheterization; she was expecting me with the greatest impatience to obtain "the great remedy" for her bladder. I immediately prescribed alcohol with some laudanum. The patient hurried her daughter to send for the remedy at once. Upon leaving I said to her that she would be entirely well. She blessed me in her old-fashioned way and looked pleased with my promise. The following morning her daughter reported that her mother urinated after the first rubbing with that remedy, which my patient called "wonderful." Since then I heard that she had not had any more trouble, but she kept copies of the prescriptions, on which she marked in German which was for kidney and which for bladder. I happened to be in her house three weeks later to attend one of her children. I took the trouble to examine her again in regard to those hysterical stigmata I mentioned above. The visual field, although not entirely normal, was considerably enlarged; not having with me a perimeter this time, I could not obtain the exact field. The plantar anæsthesia disappeared entirely. Instead she developed a pharyngeal anæsthesia.

It is four months since the patient recovered, and she has not had a relapse, but there is no assurance that she will not have one. A patient who is a degenerate and has once developed hysterical symptoms is liable to have repeated attacks of functional disorders and even to develop other neuroses.

This case appeared to me to be of great interest in regard to the rarity, character, peculiarities, diagnosis, and treatment. Perhaps there is no disease of which there has been so much written as hysteria. The number of symptoms and the peculiarities of the case are so striking that it seems the subject can hardly be exhausted. It is extremely interesting in making a diagnosis and applying a proper treatment in order to obtain the proper results. And the more there is written on the subject, the more one feels anxious to study each case.

Anuria of course, as well as oliguria and ischuria, has been observed in hysteria, but contrary to the opinion of some writers I believe it is rather a rare symptom. During the three years I spent in La Salpétrière, where the number of hysterical subjects is legion, I had an opportunity to observe but three cases of anuria. In looking up the literature for the last five years at my disposal I could find but one case reported by Guisy.[1] His case, however, differs in many points from mine, and resembles those reported by the older writers. Guisy's case can be summed up thus: The patient could urinate only half a cupful of urine; he was permeated with the odor of urine; his eyes and nostrils were congested, swollen, and red; they discharged a fluid of ammoniacal odor; examination of this fluid showed urea, pus, and mucus. The patient vomited, and the vomited fluid had the odor of urine and contained urea. There was also paresis of the left superior and inferior members. Hysterical symptoms were present. The anuria lasted twelve days.

The present case, as one can readily see, differed much, and there is the extreme interest in it that there was no vomiting, no odor of urine around the patient, no fluid from the eyes or nostrils, indeed nothing but a slight perspiration during one night, so that I could not even examine the sweating fluid. In addition to this a vesical retention followed. When the physician is not prepared for such an emergency and does not bear in his mind the possibility of hysteria, he will feel greatly embarrassed for lack of symptoms from which to make a diagnosis. If the diagnosis of similar cases is so interesting, their treatment is still more striking. In fact, what did I do to relieve the patient? Merely and simply suggestion. It is useless to mention that it was not the chloroform or the alcohol. The patient was hysterical, which condition

[1] Progrès Médical, 1895, vii., 3 s., p. 84.

is rather a psychical one, or a disease sine materia, which is of superior functional disturbance. It is therefore rational to apply a treatment which shall bear upon the patient's psychic centres. The result, as has been seen, was satisfactory. It is curious to see how complex and at the same time simple is the human cerebral condition, at least in hysteria. One feels attracted by the study of this great and exceedingly interesting functional neurosis. Let us see what we know about its pathogeny, and whether the most recent discoveries in the domain of neuropathology give a key to explain the nature of this disease, and why suggestive therapeutics give often the best results.

First of all, how and by what mechanism can anuria and vesical retention be the result of hysterical disorder? It is a well-known fact that intense moral impressions increase and decrease or suppress altogether the glandular secretions through the nerves of the cerebrospinal and sympathetic system, which nerves produce a reflex action upon the contraction or dilatation of the blood-vessels, and through them upon the excretory glands. The vaso-constrictors or vaso-dilators have their centres in the medulla and spinal cord. Any intense moral impression acts first upon the cerebral hemispheres, whence a reflex reaction takes place in the medulla and spinal cord, in which is situated the centre for the vasomotor nerves; these last send through the sympathetic system fibres to the renal plexus, which in its turn sends fibres to the muscular walls of the blood-vessels of the kidneys and contracts them; hence diminishes and even suppresses urinary secretion. The centre for the vaso-constrictor nerves, particularly of the kidneys, is situated in that portion of the gray substance of the spinal cord which is between the last dorsal vertebra and third lumbar vertebra. But this centre is dependent upon the vasomotor centre situated in the medulla. This is exactly what took place in this case. The mental tension produced by repeated attacks of illness in her family, to which she was very much attached, broke down the patient, and the reaction appeared in the urinary apparatus, first the kidneys and then the bladder, or rather the sphincter of the neck of the bladder. This last muscle, like other similar muscles, is always in a state of permanent semi-contraction which is called tonicity. This is due to the fact that the muscular fibres of the sphincter are united by nervous fibres with the motor centre of the sphincter, which is placed in the spinal cord between the fourth and sixth lumbar vertebræ (Budge). Any excitement of the centre, direct or indirect, makes the sphincter contract. In this case the impression was conceived by the cerebral hemispheres, and through a reflex reaction it was transferred to that portion of the spinal cord which contains the centre of Budge; the motor nerves going from this centre to the sphincter being put in action, produced the contraction of the muscle.

From this short discussion we can learn only of the mechanism which puts in action different centres reacting upon the organs. But how explain the initial factor, and in which way are the superior centres influenced in hysteria? Charcot said that we must consider hysteria as a disease essentially of psychical order; of the whole vast nervous apparatus it is the brain that is especially affected. At any rate, if there is an anatomical lesion, which, however, escapes as yet our investigations, we can say that this lesion is of a dynamic order, for we know that the most tenacious of hysterical manifestations are liable to disappear almost always and instantaneously from a psychical influence, as, for instance, from an intense emotion. Therefore the basis for the treatment of hysterical accidents will consist of psychical procedures. The mental state of hysterical people is characterized by its aptitude to be under the influence of suggestion. And this we mean not only during hypnotic sleep, but also in waking state. As we have seen in our case, suggestion interrupts the state of consciousness and develops other ideas. Our patient previously to the treatment was positive that she was affected with a grave disease, spoke of it everywhere and to everybody. It was therefore essential that the state of consciousness in regard to her trouble should be removed and a new idea developed. Of course, suggestion requires certain conditions, outside of which it cannot exist. A mind which has not a certain degree of weakness will not be overpowered by suggestion. Suggestion requires a disease of the personality. This explains the fixed ideas of the hysterical, which ideas are by themselves spontaneous suggestions, or at least they are automatic phenomena developed independently of will and under the influence of accidental causes. What is the cause of such a state of the nervous system in which, under the influence of a moral emotion, functional disorders take place, and why, under the influence of suggestion, do those disorders disappear?

Of all the theories there is one which has for basis the most recent studies of neuro-pathology, *i.e.*, the theory of neurons. Waldeyer was the first who suggested the idea of neurons. It is now admitted that the neuron is a unity consisting of a nervous cell with all its ramifications; while the dendrites, which are identical in their composition with the cell, are unequal to each other in their diameter and length, the ramifications of the axons are almost always dichotomous. Ramon y Cajal discovered that the neurons are independent of each other and are not continuous, so that two cells are in relation with each other through the ramifications, the ends of which are only in proximity but not in actual contact. Since it has been proven that the nervous elements are not a continuous chain and do not present a closed circle, a belief naturally arises that in order to give passage to a nervous current it is necessary that they should be in contact sometimes, and for this it is supposed that the ends of the ramifications possess amœboid movements. Rabl Rückhard first suggested amœboid movements of cells in ganglions in vertebrata.[1] Later Wiedersheim, basing his belief on Weissmann's observations concerning the movements of certain cerebral cells in leptodora hyalina, became a partisan of this theory.[2] In 1894 Lépine, in 1895 Mathias Duval applied the theory of amœboism to the intellectual phenomena. Dercum in 1896 adapted the same theory and ingeniously explained the phenomena of hysteria. At the present time this hypothesis has made great progress, and many phenomena can be explained by it. Take for instance acts of habit: in order to acquire a habit, frequently repeated efforts are indispensable; this brings often the ends of the neurons together, and as soon as relation of contact is established, then automatic action takes place. In senility the aptitude of amœboism is greatly diminished, for the neurons lose their power of expansion; the interval between them is large, the habit of contact and the transmission of nervous influence are difficult, hence cerebral or spinal memory becomes slow. The amœboism of nervous elements gives us the key of many phenomena, physiological as well as pathological. If the ramifications are simply near each other, but not continuous, we can readily understand why under any psychical influence an insignificant displacement of them is apt to destroy their contact. On the other hand, the contact can be restored under the influence of will, or of a new psychical influence, as suggestion. For example, in our case of hysterical anuria and vesical

[1] Neurolog. Centralblatt, 1890, No. 7.
[2] Anat. Anz., December, 1890.

retention a psychical influence, namely, mental tension and worry, broke the normal equilibrium of the neurons in the cerebrum and the spinal cord; some perturbation took place among them, the normal contact in some of them was interrupted, and the neurons in the neighborhood became so disturbed locally as to produce a reflex reaction upon the renal centre and the centre of the vesical sphincter; then the above-mentioned morbid manifestations took place. A new psychical phenomenon appeared, *i.e.*, suggestion, which re-established the loss of equilibrium and har-

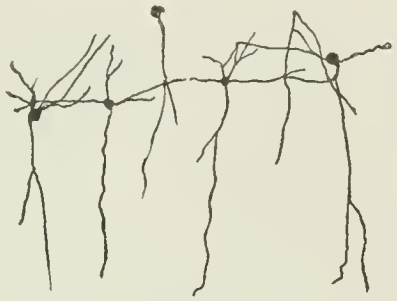

Fig. 3.

monious contact of the nerve elements, the patient recovered.

It is interesting also to know how the contact between the neurons is formed. Numberless histological researches have been made to elucidate this. The most recent are those of Stefanowska, who observed that the dendrites are provided at their ends with enlargements of ovoid shape (Fig. 3). Of course the appendices will increase considerably the surface of the free ends of the dendrites, and consequently help the contact. S. Soukhanoff corroborated the results of Stefanowska's researches, reporting his observations in the *Journal de Neurologie de Bruxelles*, April, 1898, p. 147.

WHAT ARE NECESSARY AND DESIRABLE DATA UPON HEALTH RESORTS?

By EDWARD O. OTIS, M.D.,

BOSTON.

The physician who has frequent occasion to advise his patients regarding a change of climate and the selection of a health resort is often baffled in his search for data sufficient to enable him to decide intelligently upon the applicability of any resort, under consideration, to the patient he is purposing to send away. There may have been much written about the region by both residents and visitors, but the statements are in many cases vague and unverified, and the real essential facts are wanting. Some have written with a genuine desire to state the truth; while others have exaggerated the advantages and ignored the disadvantages of a resort from a desire to make it popular. Those who, with the best intent, have attempted to describe a resort have often woefully failed to apprehend what were the necessary and desirable data—climatic, regional, and hygienic—to be determined from the point of view of a health resort.

I would make a classification of the facts and data necessary to be known in order to give a clear and working description of a health resort under two heads, the natural and the artificial. Under the former would be included the meteorological or climatic data; the elevation and distance from the sea; the configuration of the land, whether mountainous, hilly, flat, or undulating; the existence or not of water in the form of river, pond, or lake; the character of the soil and subsoil, whether dry, sandy, clayey, moist, or marshy; the character of the vegetation, and the varieties of tree, shrub, and plant; whether wooded or not; the animal and insect life—the presence of mosquitos, for instance, would be a serious objection to some persons, and, according to the new theory, might mean malaria.

Under the head of artificial facts would be included the population; the system of drainage and water supply; the existence or not of a board of health and its efficiency; the characteristics of the town as to streets, buildings, churches, public buildings, etc.; the amusements and attractions; the roads and their conditions; the accommodations, including the character of the hotels and boarding-houses, the food, sanitary arrangements, bathing facilities, expense; manner of reaching the resort, and the time and distance from one or more great cities; then the prevalent diseases and mortality, and whether reliable and skilful medical service can be obtained; and finally, what are the diseases upon which the resort is said to exercise a favorable influence; and, if the reporter is a resident physician, what has been his personal experience in the observation and treatment of these diseases.

The reader may suggest other points, but if one is in possession of the above facts—their accuracy being assured—he will be able, I believe, to form a pretty reliable estimate of the resort and judge intelligently as to its applicability to any case under consideration.

To examine in detail some of the above-enumerated facts: Under climate, various and differing data are included, or omitted, by those describing a resort, and generally, in the writer's experience and opinion, either too much or too little is given. Elaborate charts of climate are more or less perplexing to the ordinary reader and do not convey so much definite knowledge as fewer data, which should be, as far as possible, self-explanatory. I may add here, that in order to appreciate any statement of climate, a knowledge of that of the reader's residence is essential in order to comprehend fully by the comparison the differences of that of the region under consideration.

The following plan, suggested by Dr. Phillips of the United States Weather Bureau, appears to the writer to be simple and plain and yet to convey the main climatic facts of any region:

Climatic Data.	January.	July.	For Year.
Temperature:	The data for as many months as desired, or all the	months of the year in these columns.	The average for the year in this column.
Average or normal			
Average daily range			
Mean of warmest (mean maximum)			
Mean of coldest (mean minimum)			
Highest or maximum			
Lowest or minimum			
Humidity:			
Average relative			
Average absolute			
Precipitation:			
Average in inches			
Wind:			
Prevailing direction			
Average hourly velocity			
Weather:			
Average number clear days			
Largest " " "			
Smallest " " "			
Average number fair days			
Largest " " "			
Smallest " " "			
Average number cloudy days			
Largest " " "			
Smallest " " "			
Average number rainy days			
Smallest " " "			
Largest " " "			

As to the temperature, we want to know, first, what is the average daily temperature for the season in which one visits the health resort: for instance, if it

is a resort in Florida, the winter temperature; if Mount Desert, the average summer one. If an all-the-year resort like Colorado or Saranac, we want the temperature for the whole year. Next, it is important to know the average diurnal range, from which we obtain an idea of the equability of the temperature—for instance, how much colder it is at night than during the day, or when the sun is overcast than when it is clear. The mean of warmest temperature is the average daily maximum of all the days of any given month throughout the entire period of observation, be it one year or ten; for example, the mean of warmest temperature of Baltimore for thirteen years for the month of January is 40.5° F., which means that in the 403 (13×31) January days, the highest which the maximum thermometer may be expected to reach on each of these days is 40.5° F., this representing the maximum temperature of a normal January day. In the same way the mean of the coldest, or the minimum temperature of a normal day for any month, is obtained; and subtracting the one from the other we have the average daily variation or range referred to above. The highest or absolute maximum temperature is the highest reached upon any day of the given month in any year of the period of observation; and the lowest or absolute minimum is the lowest temperature reached.

These extremes, as Dr. Huntington Richards has sententiously remarked, are the "chances the invalid has got to take in any resort; they do not indicate what temperature he may expect, but what it may be his good or evil fortune to encounter." A severe frost is the "chance" in Florida, for instance; it is not expected, but occasionally it comes, and the orange-trees are frozen.

Next in importance to the purity of the air comes, perhaps, the question of moisture, whether the air is damp or dry. The average relative humidity is the best indicator of this, and is determined by dividing the absolute humidity by the amount of vapor that might exist if the air was saturated. Both the temperature and soil, as well as distance or proximity to large bodies of water, have a direct influence upon the humidity. The average rainfall is of obvious importance, and this factor should be considered in connection with the character of the soil, for if the latter is dry and porous, quickly absorbing moisture, the amount of the rainfall is of less importance than if the soil was clayey and held the water.

The direction, regularity, and velocity of the wind are extremely important facts to be noticed. From one direction the wind brings dampness, like the east wind on the Atlantic seaboard; from another dryness, like the sirocco of southern Italy, or the winds from the great Australian plains. From one direction it come fresh and pure, blowing over forest expanses or from the hills; from another, laden with dust and germs, exhausted of its ozone and deficient in oxygen. Sudden and frequent changes of the wind are generally undesirable, though, for instance, the sudden appearance of a cool sea-breeze at the sea-shore on a hot day is wholesome and refreshing. Although every region has its prevailing winds, absolute and continued regularity is found only in the region of the trade winds at such resorts as Nassau or Barbadoes, W. I.; here the northeast "trades" can be depended upon to blow daily as certainly as the sun to rise. No resort is desirable where high winds are frequent, especially for pulmonary tuberculosis; hence the importance of knowing the frequency and velocity of the wind.

Under weather data we have the average number of clear, fair, and cloudy days, as well as the rainy ones. This enables us to determine the amount of sunshine we are to expect at the resort, and the degree to which one can enjoy out-door life. Some observers note the number of hours of sunshine during the season, which perhaps is rather more accurate. The largest and smallest number of days of the different kinds of weather are again the "chances," above referred to, which we have to take; for in almost all resorts there are exceptionally bad seasons, as well as extraordinarily good ones. It is obviously of high importance to be sure of a large proportion of fair and clear days at a health resort, for, whatever the disease, it is the out-door life which is desired. On the other hand, occasional rains are desirable to cool and purify the air. If the resort described is one in the northern latitudes, like Saranac or Liberty, or of the high altitudes like Davos, it is essential to know the amount of snowfall, and the length of time snow lies continuously on the ground, and when it begins to melt in the spring. The elevation above sea-level, if at all considerable, is accompanied with especial climatic conditions which are to be noted.

Again the configuration of the land often modifies the climate, sometimes detracting from otherwise favorable climatic conditions, and sometimes neutralizing certain unfavorable ones; for example, a hill or mountain may afford protection from high winds or those blowing from an injurious quarter; or if the resort is in a valley the daily amount of sunshine may be reduced. Moderate ascents are often of value for exercise, as Brehmer utilized them at Görbersdorf for his consumptives, or as they are used in the Oertel "cur de terrain."

A hilly or undulating country is less tiresome to look upon than a dead level; it is pleasant to wonder what is beyond the hills.

Under vegetation, we want to know, in the first place, whether the region is well wooded or not, and the extent and character of the forests, if they exist. The fir, pine, spruce, and other evergreen trees are generally considered an advantage to a health resort on account of their balsamic exhalations, their shade, and the æsthetic effect. Arcachon in France, Bournemouth in England, Lakewood and the southern pine belt in this country are illustrations of resorts in the midst of pines. Görbersdorf in Germany and the Adirondacks are in the region of the fir and spruce.

Second, some account of the other forms of vegetation should be given, especially the flora. The invalid may happen to be a botanist, and a rich and varied flora may afford him unending delight. If he is a sufferer from hay fever, a knowledge of the plant life is important; if an entomologist or zoologist he will want to know something of the insect and animal life to be found there.

It is evident that dryness of soil and subsoil is desirable, and that any large amount of stagnant water in marsh, lake, or pond is undesirable, on account of the increased humidity and the possibilities of malaria.

After a consideration of the natural conditions of a health resort, we have to examine next the artificial ones, as I have termed them. What facilities exist for comfortable living, without which the best of climatic conditions are likely to prove elusive? The invalid requires good food, properly cooked; a well-ventilated and sunny bedroom and a comfortable bed; suitable and sufficient attendance, good sanitary arrangements; facilities for sitting or reclining out of doors, if the open-air "Liegekur" is to be taken; and if it is a resort for pulmonary tuberculosis some assurance that his neighbors will properly dispose of their sputum. He must be sure of obtaining pure drinking-water, and know that the sewage is safely disposed of, that the risk from the zymotic diseases may be avoided. An intelligent and efficient local board of health is quite indispensable at a health resort; for instance, hotels, boarding-houses, or rented cottages, receiving consumptives, should be under the supervision of

such a board, by application to which one can be sure that a room or cottage which has been occupied by a consumptive has been satisfactorily renovated and disinfected. At Cannes, France, the health authorities, in conjunction with the physicians, do this. In many other ways the invalid can be protected by a capable health board from avoidable dangers of contagion.

The amusements and diversions the resort affords should receive mention, and not be exaggerated as is too often the case. One cannot live by climate alone, but must have something to occupy his mind when away from the sweet influences of home and the usual routine of life, and depressed by illness. The outdoor diversions are the ones to which especial attention should be given, for in the majority of cases the invalid is expected to spend the greater portion of his time in the open air. The amusements of the quieter kind will be the ones most applicable to the patient—driving, walking, shooting, fishing, etc. The condition and extent of the roads are also to be mentioned. Is there a library; and are there schools? What are the churches? For many prefer to go where a church of their own denomination is to be found. A most important and in many cases decisive fact to be known is the probable expense; about what will it all cost? For what price can one obtain comfortable accommodations, and what are the other necessary expenses? No resort should be recommended which does not contain one or more good physicians, known either by reputation or personally to the physician sending the patient there, and to whom the invalid should be referred by a note of introduction, briefly stating the case.

If the results of cases treated at a resort can be presented by physicians practising there, they will indicate, as nothing else can, the actual benefits to be expected from a residence at the resort, for whatever disease its climate is recommended. The careful results published by the late Dr. Geddings, of Aiken, those of Dr. Trudeau, of Saranac, and of Drs. Fiske and Solly, of Colorado, are admirable illustrations of this. Simply to make the statement that such a resort is beneficial in such and such diseases, without facts and results, carries but little weight, when one considers how inconsiderately this claim is often made.

The writer is well aware that to obtain all the data and facts enumerated above, with accuracy and a strict adherence to truth, requires long experience with a health resort, and painstaking observations. Indeed some of the data can be collected only by observations which must extend over a series of years, like those of climate; but others are always at hand, like those relative to the soil and vegetation. It is, however, some such plan as here suggested which should be kept in view, and every year of experience will add something toward the completeness of the record.

The therapeutic value of a change of climate, and the many advantages of health resorts, are becoming more and more appreciated by the profession. With this greater appreciation, however, comes the greater desire to be in possession of sufficient and definite knowledge of the various health resorts, so that they can be prescribed with something of the same accuracy with which one prescribes a drug or other treatment. If one has a new remedy to offer, its composition, physiological action, and the effects of its use in the disease for which it is advocated, are given. So it must be with a health resort, so far as the intrinsic conditions will allow. At all events, while the knowledge is accumulating to render such a description possible, let not hasty and unproved generalizations be given for facts. State what is known, and wait for more evidence and the results of more extended observations and longer experience.

TUMOR ALBUS.[1]

By FRANK E. PECKHAM, M.D.,
ORTHOPEDIC SURGEON, RHODE ISLAND HOSPITAL.

Tumor albus, or white swelling, is a term applied to a chronic tuberculosis of the knee joint. This process may first attack the epiphysis of the long bones either above or below the joint. It may attack the patella, or it may first appear in the synovial membranes.

In 1898 Dr. Nichols, of Boston, presented a very elaborate paper before the American Orthopedic Association, proving that in over one hundred and twenty tuberculous joints examined by him the disease had begun in the epiphysis. From this he reasoned that in all probability this was the original point of attack in the majority if not all cases. This was rather difficult to believe, because clinically joints had been opened, the gelatinous tuberculous material removed, the bone found to be in many cases not seriously if at all damaged, and the operation of arthrectomy (sometimes spoken of as erasion) being entirely sufficient to limit the progress of the disease. Since that time clinical experience has become still more definite, and the *x*-ray photographs have begun to show that undoubtedly there are many cases that do not begin in the epiphysis, but rather in the synovial membranes or joint surfaces.

The symptoms of this disease come on very slowly, and the most prominent ones are heat, swelling, tenderness, and the presence of fluid causing distention. When fluid is not present and the joint is enlarged it has a peculiar boggy feeling to the touch, and the tissues are raised above the patella. When the joint is opened this is found to be due to the presence of a gelatinous tuberculous condition of the membranes, and this is quite characteristic of tuberculous knees in the early and acute stages, whether with or without the presence of fluid. The inner condyle is very apt to be more enlarged than the outer, causing a condition similar to knock-knee. These symptoms coming on also cause lameness, which may be intermittent in the very early stages. With increasing irritability the flexor muscles slowly become contracted, causing flexion and subluxation, two characteristic deformities. The muscles above and below the knee become atrophied. In this stage of the disease there is very apt to be an actual lengthening of the leg due to an overgrowth, the epiphysis being stimulated to greater activity for a time. The temperature of the joint is elevated, the difference between the two knees being perceptible to the sense of touch. At first when the patient is still bearing weight on the leg there is slight pain, which becomes more and more aggravated and may be excruciating if treatment is delayed. The face also begins to be an index to the general condition, becoming anxious and careworn, and sleep may be interfered with, although the "night cries" of hip disease are absent. If treatment be delayed then the constitutional symptoms appear—fever, debility, emaciation, loss of appetite, and loss of flesh. Abscesses may complicate knee-joint disease, but usually in the more acute forms or in the neglected cases.

Without entering into an exhaustive differential diagnosis, I shall mention two or three diseases which most commonly give trouble in ruling out. Synovitis in the early stages, particularly if the general physical condition is a little run down, may be difficult or even impossible to distinguish absolutely. In synovitis the patella can be depressed until it is felt to strike the femur beneath, while in tuberculosis the swelling is a boggy thickening surrounding the patella rather than floating it as fluid would do. In synovitis motion is not interfered with so much, and atrophy is not present.

[1] Read before the Providence Clinical Club, May 2, 1900.

In acute articular rheumatism there is a sudden onset with fever, and other joints may become involved, while ordinarily white swelling is an insidious affair. In the chronic forms of rheumatism greater care is necessary in differentiating, and it may be even impossible to do so clinically.

Rheumatoid arthritis is another affection which may closely stimulate white swelling. With this disease the enlargement at the joint is bony and is more apt to be of a spindle-shape. The ends of the bones become more or less eroded, and motion is liable to cause a grating which can be felt when the hand is placed upon the knee, and in many cases the sound is audible. More than one joint is liable to be affected.

Hysterical joints may give trouble at times, but careful examination at different times should reveal the true nature of the affection.

The treatment of tumor albus naturally resolves itself into conservative and operative. The conservative method includes a general tonic treatment which would be of value in any wasting disease. The mechanical part of the treatment includes fixation and protection. Fixation is best obtained by a plaster-of-Paris bandage extending from the ankle to the groin, and in some of the more sensitive cases even the foot should be included. Other materials may be used, and the leg may be splinted, but when one becomes thoroughly accustomed to the use of plaster of Paris there is nothing which gives such complete satisfaction. Later in the disease and during convalescence a leather corset may be fitted, lacing up in front, thus giving a much lighter support and one that can be removed and the skin cleansed every day.

Protection is accomplished by keeping the weight from the diseased leg. The patient in a great many cases will get along with just the plaster of Paris and a pair of crutches, swinging the leg during the act of walking. A high sole may be applied to the shoe of the well leg, thus raising the patient up two inches. At the same time a splint may be applied to the diseased leg, thus transferring the weight to the perineum when walking. This splint may be worn over the plaster of Paris or leather corset, and during convalescence the splint alone may suffice.

In the early stages various external applications were recommended in the text-books, but I never yet saw any good results from such treatment, and I fail to see how anything applied externally can have any effect whatever upon tubercle bacilli deep within a joint. If such a thing were possible, certainly the treatment in other tuberculous affections, such as tuberculous meningitis, should show better results.

Operative procedures become necessary in the cases that do badly under conservative treatment. The operation which I most frequently do, especially in children, is arthrectomy. The joint is thoroughly opened by a circular incision extending through the ligamentum patellæ, a flap being formed which, when elevated, exposes the supra-patellar space. With this free opening every portion of the joint can be inspected and every portion of tuberculous material removed, and if the bone is found to be seriously diseased everything is already thoroughly exposed for an excision, and no time need be lost. In doing a simple arthrectomy my experience is that the curette is of very little value, as it slips over the tough, gelatinous-like material without taking off very much of it; but with a pair of mouse-tooth forceps and curved scissors it can be removed with much greater facility. The semilunar cartilages will usually be found diseased, and the space above the patella and beneath the rectus muscle must always be thoroughly explored, and will usually be found filled with tuberculous material. It is impossible to know in any given case whether all disease has been removed, but a thorough operation must be done. The ligamentum patellæ, which is divided in this operation, readily unites, as is demonstrated in cases operated upon a second time.

If, on opening, the bone is found to be extensively invaded and the patient is an adult, excision should be done immediately, while in children oftentimes the curette will be sufficient. In the adult the bone has attained its growth, and so saving the epiphysis is not of such importance as in a child.

Arthrectomy is the most usual operation, excision coming next, while amputation would be necessary only as a life-saving measure.

I shall now submit a few illustrative cases:

Case I.—The first patient, a little girl, A. G——, now aged seven years, first came under observation November 21, 1896. The disease had been present then six months, and had involved both knees and both ankles. There were beginning contractures of the hamstring muscles, with swelling of knees and ankles. She was unable to walk on account of pain; the child was crying out at night, and considerable loss of flesh had taken place. This case has been treated through the whole course of the disease as an out-patient at the hospital, and plaster of Paris has been the only method used. All treatment ceased December 30, 1899, about three years in duration, and the patient now attends school. There is no thickening about the joint; there is normal motion at the ankles, while at the knee flexion is possible up to a right angle, which allows her to sit down easily. In walking about the room nothing unusual is observed.

Case II.—The next patient is K. McL——, now aged nine years. She first came under observation November 5, 1896, the disease having already existed one year. This case did not do well, and early in 1898 arthrectomy was done, followed by plaster-of-Paris splint until June, 1899, when all treatment was omitted, almost one year ago. The knee is stiff and slightly flexed, and the diseased leg measures now three-eighths of an inch longer than the sound leg. She walks and runs easily.

Case III.—This result is also an excellent one. This boy, J. H——, aged ten years, came under observation November 10, 1896, the disease having existed for four months. Two operations, both of them arthrectomies, have been done; the first one early in 1898, and the second one in the fall of 1898. Plaster of Paris was omitted in the early fall of 1899, and the boy has been walking on the leg ever since. The knee is slightly flexed in this case also.

I wish now to speak of two cases in adult life in which arthrectomy was entirely sufficient. There are a number of these cases, but two will be sufficient, and they are interesting as well as the cases of the children, showing that the disease in many cases must begin in the synovial membranes and not in the epiphysis.

Case IV.—M. M——, aged twenty-four years, came under observation November 3, 1897. His knee had been troublesome for over a year on account of pain, and at times the joint would become "locked." In March, 1897, a piece of floating cartilage had been removed, and in the latter part of October the joint had been aspirated. As the joint looked bad an arthrectomy was done November 8, 1897, and a large quantity of sero-purulent fluid was found in addition to the usual gelatinous condition. The bone was only superficially involved, and hence an excision was not done. The joint was drained and continued to discharge a small quantity of serous fluid until May, 1898, when it closed and was apparently perfectly solid. The man works at present in a coal-yard, shovelling, and says he has had no trouble since leaving the hospital three years ago.

Case V.—O. T——, a man twenty-one years of age, came under observation February 19, 1900, with the history of a tuberculous knee of four years' duration. He had been walking about on it all this time, but it had become so painful that he had to give up and go to bed. On March 5, 1900, the joint was opened, the tuberculous material all cleaned out, and the bone found perfectly healthy; consequently only an arthrectomy was done. The wound was closed practically without drainage. There was no trouble whatever with healing, and the patient was discharged on April 14th, with a perfectly solid joint. Plaster will be continued for a short while, when the leg should be all right without any further treatment.

A FURTHER REPORT UPON THE USE OF PURE CARBOLIC ACID IN THE TREATMENT OF MASTOID WOUNDS AND CHRONIC SUPPURATION OF THE MIDDLE EAR.[1]

By WENDELL C. PHILLIPS, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, AURAL DEPARTMENT; PROFESSOR OF DISEASES OF THE EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

At the fifth annual meeting of this society I called your attention to the use of pure carbolic acid in mastoid wounds and in chronic suppurations of the middle ear. The paper[2] gave a short résumé of Powell's article on "Carbolic Acid in Surgery,"[3] wherein he had demonstrated that a ninety-five-per-cent. solution of the crystals of carbolic acid could be rubbed freely on the hands and allowed to remain for a few seconds with no unpleasant effects, providing the hands were rinsed with pure alcohol; in other words, he had shown that alcohol is a perfect antidote for carbolic acid.

At the time the previous paper was presented, I had made use of this drug for three months only in the treatment of mastoid wounds and chronic suppurative otitis media in which necrosis existed, and in the sinuses so often found in mastoid wounds which are so difficult to heal; I also presented a convenient atomizer for spraying the acid when it was required in attic cases.

Several of the cases presented at that time had resisted all methods of treatment, but with the use of carbolic acid healing rapidly took place. From the number of cases in which it had been used, six were reported, in all of which the patients have remained well up to the present date. During the past year I have continued the use of carbolic acid both in private and hospital practice, and am able to give a fuller report as to its benefits. My cases have been about the same as those reported before, excepting that I have used it upon the denuded surfaces after ossiculectomies and also in burrowing pus sacs accompanying mastoid suppurations. Some of these pus sacs extended well down into the sterno-cleido-mastoid muscle, and others had burrowed downward and backward upon the external surface of the cranium. I have used it freely in these latter cases, and cannot say too much as to the favorable results obtained. After emptying the pus cavities freely I used the carbolic acid with considerable freedom, making use of a cotton carrier and leaving the cotton rather loose at the point. I swab out these cavities with the acid. One improvement in its use in this connection seems to have been obtained from leaving the acid a longer time in contact with the tissues before using the alcohol. I often leave the carbolic acid for from thirty to sixty seconds before resorting to the alcohol. This seems to me to be the more rational method, giving the carbolic acid more time to produce its effect upon the necrosed tissues with which it comes in contact.

In the pus sacs in which I have used the carbolic acid, I have not in any single instance been obliged to make any operation for secondary abscesses. At this moment I can recall four ossiculectomies in which I have made use of carbolic acid to destroy any resultant necrosis. I might state here that I never perform ossiculectomy except in those chronic suppurations which have resisted all forms of local medication for a reasonable period of time.

In all these cases I believe pure carbolic acid has had a beneficial effect, although I am fully aware that many of these patients recover as a result of the removal of the ossicles alone; at least I have seen no ill effects from its use in this class of cases, and I have come to believe that there is a more rapid healing when carbolic acid is employed. I might further add that in no instance has the use of carbolic acid in the cases above described been followed by any unfavorable reaction or any untoward symptoms, so that if applied even with considerable freedom one need have no fear of doing harm, of course bearing in mind the fact that the acid is thoroughly destroyed by the subsequent free application of alcohol.

I have the following note from Dr. Parker, house surgeon to the Manhattan Eye and Ear Hospital, giving in a few words the result of his experience with the acid. Dr. Parker gives his experience in effect as follows: He has used pure carbolic acid, followed by alcohol, for the past six months in about twenty cases that have been operated on for mastoiditis, and has observed that the discharge has been markedly lessened by its use in cases in which other cauterizing agents had failed. To quote his words: "Under its use, areas of necrosed bone have taken on a healthy healing-process, sluggish granulations have been stimulated to healthy activity, and in many cases secondary operations have been avoided. It has been particularly valuable when used by means of the spray; in discharge of the middle ear, many cases of persistent discharge have been entirely stopped."

[3] MEDICAL RECORD, March 11, 1899.

Experiments on the Resistant Powers of the Plague Bacillus to Cold.—H. Noguchi, of the General Hospital in New-Chwang, China, has found that the plague bacillus is not devitalized by a three weeks' exposure to a temperature of 24° C. below zero. This bacillus can develop slowly but steadily, at a temperature of from 20° C. to 37° C. Near the freezing-point it remains inert. Chinese houses, with their bad ventilation and other unhygienic conditions, furnish favorable conditions for the development of the plague bacillus. Mice and some other animals (excepting birds and swine, which are immune) help to propagate the plague. It is difficult to enforce sanitary measures in China, where legislation and police protection give no assistance, and the author thinks it safer for foreigners to isolate themselves than to try to isolate the Chinese. Their houses should be under strict sanitary inspection, and a public market should be started for their provisions apart from the town.—*The Sei-i-Kwai Medical Journal*, Tokio, May 31, 1900.

The Occurrence of a Peculiarly Altered Blood Pigment in the Urine of Paroxysmal Hemoglobinuria.—Jolles relates the case of a patient who for eight years has suffered from occasional attacks of hæmoglobinuria. These never occur in summer, but only in cold weather, when they are ushered in by

painful, chilly sensations in the extremities and a sense of oppression, which symptoms are speedily followed by the characteristic discoloration of the urine. In examining this the author found a body which does not give the spectroscopic field typical of any of the blood pigments hitherto studied, and which on boiling coagulates without undergoing decomposition and yields crystals of hæmin. It is also precipitated unchanged by ethyl alcohol, amyl alcohol, and ether, while acetic and hydrochloric acids act by splitting it into two components, one of which, a peptone-like substance, goes into solution, while the other, containing iron and phosphorus, is thrown down and does not yield the Teichmann's hæmin crystals.—*Wiener klinische Rundschau*, July 8, 1900.

A Channel of Infection in Man.—Aron endeavors to explain the variations in individual susceptibility to infection by the zymotic diseases by giving the tonsils an important rôle as portals of entry for the contagium. Accepting this view it is easy to believe that greater or less resisting-power to invasion by disease goes more or less hand-in-hand with differences in the structure and conformation of those organs. It is particularly the tonsillar crypts that furnish suitable lurking-places for bacteria of all sorts, and it is well known that in some persons these are abnormally numerous and deeply placed. It seems well proven that from this point infectious material can find its way directly into the blood stream without first having had to pass through the successive filter-beds existing in the shape of the numerous cervical lymph nodes.—*Wiener klinische Rundschau*, July 8, 1900.

Diagnosis of Tuberculosis in Chronic Aural Suppurations.—G. Ferreri lays down the following propositions: (1) It is necessary from a diagnostic as well as a therapeutic point of view to determine the true nature of a chronic suppuration of the ear when there is a suspicion of tuberculosis. (2) As a careful and exact means of establishing the existence of an osseous caries an opinion from a dermatologist may be of the greatest value. (3) As the presence of caries is not absolute testimony in favor of the existence of a specific tuberculous lesion, we ought to call in to our aid all other possible means of research. (4) In the present uncertainty of our knowledge the best course to follow is to make the tuberculin test, and to remove for microscopic examination the pre-mastoid lymphatic ganglion.—*Archivio Italiano di Otologia, etc.*, July 7, 1900.

Clinical Forms of Purulent Rhinitis; their Pathology and Treatment.—C. de Rossi says that the essential principle of treatment is comprehended in the words "non nocere." The mucosa invaded by pus germs is easily vulnerable. If one touches the mucosa too roughly, it bleeds easily, and if the young epithelia which are forming are detached, a new channel is opened for the micro-organisms; moreover hemorrhage, however slight, interferes with the exact and efficient application of topical agents. The circumscribed forms of purulent rhinitis, which lead to ulcerations, perichondritis, septal abscess, carious or necrotic osteitis, etc., require surgical treatment. Ordinarily the removal of necrotic portions and the application of the electro-cautery are sufficient to effect this.—*Archivio Italiano di Otologia, etc.*, July 7, 1900.

Ulcerations of the Tonsils.—Brindel and Raoult divide these into primary (such as ulcerative lacunar tonsillitis, pseudo-diphtheritic, gangrenous, ulcero-membranous, etc.), secondary (infectious maladies as diphtheria, typhoid, the exanthemata, and tuberculosis), symptomatic (as those of lupus, syphilis, and scrofula), and ulcerations of malignant tumors. The term ulceration denotes a loss of substance at least of the epithelium, and more often of the basement membrane and underlying tissue. Ulcerations should be distinguished from mere erosions. The particular class to which a given case belongs requires a consideration of the entire history of the case and a careful watching of the progress of the lesion in its different stages.—*Revue Hebdomadaire de Laryngologie, etc.*, June 23, 1900.

The Etiology of Malignant Tumors.—Ziem reports a series of cases of malignant tumors of the upper air tract, all having the common features of traumatism and the antecedent existence of a purulent discharge. He believes that this combination of factors is the frequent cause of the development of malignant growths in the upper air passages at least. The likelihood of their development is still further increased if with the existence of the discharge there is an infectious complication, such as syphilis, erysipelas, influenza, typhoid, and possibly also malaria.—*Revue Hebdomadaire de Laryngologie, etc.*, May 9, 1900.

Septic Pyohæmic Otitis.—G. Laurens lays down the following rules for guidance in treatment: Given a pyæmia in the course of an acute otitis without any localization in the mastoid, and without grave infectious symptoms, we should puncture the drum so as to provide for perfect drainage and care for the general condition; if mastoiditis is present, the apophysis must be opened and the sinus uncovered preparatory to examination; finally, if the pyæmia runs its course without involving the mastoid, but with grave symptoms of severe general infection, we must open the antrum, and if it is healthy we should proceed as in the case of the sinus; if the exploring needle withdraws blood, abstain from opening; if there is thrombosis, incise the sinus after previous ligation of the jugular.—*Revue Hebdomadaire de Laryngologie, etc.*, July 7, 1900.

The Treatment of Burns.—G. S. Armstrong thus summarizes the appropriate treatment for burns, he having in the past two years treated one hundred and seventy-six cases, chiefly of the second degree, one caused by boiling oil, and all the others by flying metal. Water or solutions containing water are bad; vaseline acts badly; the application of cotton lint, gauze, or any dressing with a rough surface is inexcusable. (1) Cut away with particular care every portion of every bleb, even the smallest. See that no margin is left under which burrowing may take place. (2) Apply castor oil ninety-five per cent. and balsam of Peru five per cent., or lanolin. (3) Cover this with gutta-percha or oiled silk, perforated or not. (4) The molecular death and separation of tissues will cause an accumulation under the gutta-percha, which must be removed each day by gentle mopping with absorbent cotton. This is easily done, without disturbing the granulations or causing bleeding. (5) A small portion of cases improve more readily during the later stages under dry boric acid.—*Medical Sentinel*, July, 1900.

Acute Mastoiditis Following Infectious Diseases.—J. W. Murphy says that about twenty per cent. of the children suffering from an infectious disease have, at some time during the course of the disease, an infection of the mucous membrane lining the tympanum and mastoid antrum. If toward the close of an attack of one of the infectious diseases there is a sudden rise of temperature, with restlessness, especially marked at night, it indicates some new focus of infection. The drum membrane may be found inflamed, and pain on pressure over the mastoid, or swelling in that region, will point to involvement of the middle ear.

One of the most reliable symptoms of involvement of the pneumatic spaces of the mastoid is swelling or bogginess of the posterior superior wall of the external auditory canal, near its junction with Schrapnell's membrane. If after the continuous action of heat or cold (not poultices) for thirty-six hours there are still much pain and tenderness over the mastoid, we should not wait longer, but open up the mastoid cells by means of Schwartze's mastoid operation—opening the antrum and pneumatic spaces of the mastoid.—*Columbus Medical Journal*, July, 1900.

Experimental Researches on the Latero-lateral Anastomoses of the Vas Deferens.—Enrico Trocello has conducted experiments with a view of determining the best treatment for establishing the continuity and permeability of the vas deferens in cases of complete transverse wounds of the duct. He finds that the indications are met by means of a latero-lateral anastomosis of the two stumps and closure of the end of the duct. He describes the methods adopted, and claims that the results are excellent.—*Il Policlinico*, June 15, 1900.

The Treatment of Movable Kidney.—D. Biondi in eleven cases of nephrorrhaphy has made an incision in Petit's triangle between the posterior margin of the oblique and latissimus dorsi muscles. In this situation all that is needed is to cut down on the anterior margin of the quadratus lumborum through the anterior and posterior folds of the aponeurosis of the transversalis, to reach the adipose capsule of the kidney. He then removes the adipose and fibrous capsule, corrects any anteflexion of the kidney, and puts it in place, where he keeps it by tampons of gauze, which are stuffed into the space below the kidney. When the gauze is withdrawn six to eight days later, the kidney is found to be firmly fixed in place. The operation is innocuous and efficacious.—*La Riforma Medica*, July 10, 1900.

Non-Tabetic Lesions of the Posterior Columns of the Spinal Cord.—E. A. Homén divides these affections into three groups: (1) Those caused directly by neuritis, due either to purely anatomical nerve lesions, or to noxious agents such as toxins or microbes; (2) those co-ordinated to neuritis, that is to say, those in which the same noxious agent can affect the intramedullary tract, as well as the peripheral portions, or else both at once; (3) those entirely independent of neurons or of fibres, but in close relation to the blood-vessels. In chronic alcoholism there may be affection of exogenous sensory fibres of Goll's column, with peripheral neuritis. In eleven cases of cancer there was rarely alteration of the posterior extra-medullary roots, but there was of the intra-medullary. In grave anæmia the lesions are most pronounced in the posterior columns; in senile marasmus there is thickening of the neuroglia, with corresponding atrophy of the nerve fibres, principally in the posterior columns and around blood-vessels. Myelitic lesions in acute infections and purely syphilitic lesions of the spine show no special predilection for the posterior columns of the cord.—*Finska Läkaresällskapets Handlingar*, June, 1900.

An Unusual Case of Prolonged Intubation.—D. Tanturri describes a case in which intubation was prolonged to one hundred and thirty-six days. In his conclusions he states that a possible complication of croup may be a peri-tracheal-laryngeal abscess, followed perhaps by partial necrosis of the cricoid. In acute laryngeal stenosis of long duration intubation is a valuable resource. The tube may be left for a long time in the larynx without harm, provided that it is of the proper size and material and that the surgeon bear in mind the delicacy of the structures upon which he is working. O'Dwyer's fenestrated tube is of the greatest value in granulations of the cricoid. Ichthyol with gelatin is an excellent medicament for the larynx in cases of intubation. Meat gelatin is a good food in these cases.—*Giornale Internazionale delle Scienze Mediche*, June 30, 1900.

The Effect of Fatigue in Modifying the Minute Structure of Kidneys and Liver.—Guido Guerini by experimentation upon animals has found that as an effect of great exertion the protoplasm of many cells of the convoluted tubules become homogeneous and granular. The cells increase in size. Still greater fatigue causes them to break down and fill the lumen with a fine detritus. The changes in the liver cells are very similar, consisting in the first place of turbidity and increase in size of the cell contents, and under greater stress of rarefaction and sponginess. The cells contain much bile pigment.—*La Riforma Medica*, July 9, 1900.

Gout as a Function-Failure.—S. W. MacIlwaine enters a protest against the narrow view so frequently expressed that gout finds its essential expression in joint disturbance. We should rather take a broader view and look upon it as a failure of the metabolic functions under conditions that produce no such untoward results in the majority of people. The essence of the disease is the production of imperfectly soluble waste products difficult of elimination. The cause of gout is therefore function failure. It is intrinsic in origin, and treatment must be directed to the individual, to the re-establishment of his deranged functions. Roughly speaking, the bulk of the metabolism occurs in the muscles; further, the commencing channels of excretion are emptied by vigorous muscular contraction. Exercise flushes the joints with their viscid and sluggish fluids. Experience teaches us that a man on a rational diet, and in the enjoyment of exercise necessitating the daily vigorous use of all his muscles, does not suffer from gout.—*Medical Press and Circular*, July 18, 1900.

The Pathology and Etiology of Acute Articular Rheumatism.—J. C. Young discusses this question from the standpoint of the effect of the disease as bearing on the question of life insurance. His inferences are as follows: (1) If the disease has occurred in the ancestor and not in the applicant it need not be considered, for heredity can be traced only in about thirty per cent. of the cases anyhow; and if a parent has had rheumatism, it by no means follows that his child must suffer from it. On the other hand, if such an applicant has himself had an attack already, the probability of recurrence is thereby greatly enhanced. (2) As a rule, the earlier the age at which a primary attack occurs, the greater the likelihood of repeated attacks, the greater their severity, and the greater the probability of cardiac complications. The later the age, the less the danger to be apprehended from the consequences which the disease engenders. (3) Occupations calling for great muscular exertion, with consequent fatigue and free perspiration, and particularly when the applicant is exposed to sudden chilling, produce more than half the cases, and if he has already had an attack, persistence in such occupation greatly increases the risk. (4) Conditions of living which favor a lowering of tone of the nervous system, or produce a uric-acid diathesis, or serve to enfeeble the muscular system, increase the susceptibility of the individual and augment the chances of recurrence. So, too, with diseases which lower bodily resistance. (5) A combination of two or more of these elements just so far increases the probability of recurrence and impairs a risk in the same proportion.—*Medical Examiner and Practitioner*, July, 1900.

THE PROGNOSIS OF GLYCOSURIA AND DIABETES.

THE interpretation applied to the presence of sugar in the urine depends essentially upon whether it is to be looked upon as a simple glycosuria or as a symptom of diabetes. On the one hand, a transitory failure on the part of the sugar-assimilative functions of the organism may be concluded to exist, while, on the other, the manifestation is to be looked upon as a symptom of an incurable disease. The prognosis must necessarily vary in accordance with the pathology of the morbid process in operation. On the basis of a considerable personal experience, Hirschfeld (*Berliner klinische Wochenschrift*, 1900, Nos. 25 and 26) expresses dissent from the prevailing view with regard to the curability of diabetes. Improvement, he maintains, is frequently observed, even in severe cases of diabetes, and it may at times reach a degree sufficient to transform a severe into a mild case.

From observations in some two hundred and fifty cases of diabetes, Hirschfeld was impressed with the variability of the glycosuria, improvement taking place far more commonly than aggravation. This was especially marked in mild cases and less so in severe. In analyzing the cases an attempt was made to determine in how far prognostic conclusions could be reached from the severity of the functional disturbance in the individual case. Associated conditions, such as the presence of nervous symptoms or complications, afford no indication of the severity of the diabetes. Only from the degree of the glycosuria itself does the prognosis as to the severity of the diabetes seem possible. In this connection the question arises, When can such a degree of improvement be hoped for that the urine will remain permanently free from sugar? The improvement that follows the withdrawal of carbohydrates sets in only in the course of a few months, although the assimilative power is increased immediately afterward. Improvement, further, is less commonly to be expected if the disease is of long standing, and it may be assumed that under such conditions the curative effects of antidiabetic diet are to a certain degree exhausted. Nevertheless, transitory improvement in assimilative power may be brought about by temporary rigid restriction of the diet and active muscular exercise. In general, it may be said that if in a case of long standing such conditions cannot be established, in spite of restriction of carbohydrates, permanent improvement cannot be hoped for. Exacerbations are due principally to overloading the organism with an excess of carbohydrates. Such exacerbations develop slowly, *i.e.*, in the course of months or even of years, in contradistinction from changes due to extraneous circumstances. At times, it is true, the disease increases in severity without external cause. Such conditions are present principally in young patients, and rarely after the thirtieth year.

In addition to glycosuria, there may be an increased elimination of acetone. In severe cases there is an increased amount of acid present in the urine. It is a debatable question whether diabetic coma is to be looked upon as an acid intoxication. In mild cases the elimination of acetone is but little, if at all, increased. If the amount is large, diacetic acid also is usually demonstrable by the ferric-chloride reaction. Progressive increase in acetonuria is of unfavorable prognostic significance. The patient may feel well, but coma is readily induced, as, for instance, by physical effort or inanition. It is of general prognostic importance that acetonuria, in contrast with glycosuria, more frequently exhibits a tendency to spontaneous increase. In some cases, it is true, the exacerbations are also induced by unfavorable external conditions and by disease states that exert an unfavorable influence upon the glycosuria. A third metabolic disturbance is to be taken into consideration, viz., deficient absorption of the food. This of itself renders the prognosis unfavorable, as with imperfect utilization of proteids and fats maintenance of the bodily weight is difficult.

Among extraneous conditions capable of increasing glycosuria, intercurrent disease especially is worthy of mention. Exhausting disease at times, though not always, to a certain degree displaces the glycosuria. Disease of the kidneys, especially, exerts such an influence. On the other hand, the opposite effect also is sometimes observed. The hyponutrition attending most diseases causes diminution in the glycosuria in a large majority of cases of diabetes. In Hirschfeld's experience, however, the majority of febrile diseases were without any influence on the glycosuria. To this rule influenza constitutes an exception in many cases, often causing increase in the glycosuria and coma. Painful attacks of colic, with transitory diarrhœa or constipation, may make their appearance early in cases subsequently attended with deficient absorption. A directly deleterious effect is exerted also by those disorders considered peculiar to diabetes, viz., furuncle, carbuncle, gangrene. In some cases, however, the excretion of sugar is slight. Psychic influences, particularly severe fright, have a bad effect on diabetes, as have also painful affections, biliary calculi, renal calculi, hypochondriacal delusions.

Cardiac enfeeblement may be a manifestation of diabetes, and it will under such circumstances be relieved by antidiabetic diet. An appearance of well-preserved nutrition is, as a rule, an indication that the disease is not progressing; but to this there are numerous exceptions. Increase in polyuria is sometimes indicative of aggravation of diabetic functional dis-

turbance. In Hirschfeld's opinion, alcoholism or alcoholic intoxication can scarcely be considered a factor in the etiology of diabetes. He holds that the essential point to be borne in mind is that in cases of diabetes glycosuria is a most variable symptom, with a tendency, especially in recent cases, to undergo spontaneous improvement, unless the organism be overwhelmed with carbohydrates. As to the recognition of alimentary glycosuria as a distinct affection, its brief duration, and the lower percentage of sugar, as well as the absence of characteristic symptoms, such as polyuria and nervous manifestations, can no longer be considered as decisive, while the evidence goes to show that its clinical course is identical with that of diabetes. Finally, Hirschfeld prefers to speak of relative, rather than absolute, recovery or cure, and this he considers accomplished if the patient can tolerate constantly 200 gm. of carbohydrates daily without the appearance of sugar in the urine.

CLIMATE AND DISEASES OF CHINA.

If the war now being waged by the civilized world against China should be a lengthy one, it will be incumbent upon the governments of the several powers engaged to pay particular attention to the numbers, composition, and equipment of the medical and nursing staff. By neglect of this most necessary branch of the military service serious results are certain to follow. This has been recently evidenced in a conclusive manner among the British troops in South Africa.

The climate of China is, according to trustworthy accounts, and especially in those portions in which American soldiers will be called upon to operate, decidedly insalubrious to men of the white race. In the region in which are situated Peking, Tien-Tsin, and Chefoo, the heat in the summer season is tropical, while during three winter months the thermometer goes down as low as 15 degrees Centigrade below zero. These extremes of temperature are characteristic of this part of the Middle Kingdom and peculiarly so of Peking, and consequently very trying to those not acclimatized. Rain never falls in winter, and snow but on rare occasions. As a matter of fact the rainfall in and about Peking is slight. The greatest extremes of climate are exhibited in Shan-Si and portions of Shan-Tung. The rivers and streams in these districts are deeply frozen, as is the Gulf of Pechili along the coast line to eight or ten miles from shore. The change from heat to cold and vice versa is extremely sudden, and is therefore certain to have a bad effect upon the health of foreigners.

The New York *Herald* of August 12th says, in an article referring to the diseases of Northern China, "that on account of the extreme character of the climate, the diseases follow the seasons in a well-marked order. During winter, besides the direct results of the action of cold, such as acute affections of the lungs and rheumatism, typhoid epidemics are noted, as well as typhus fever and diphtheria; their development is due evidently to the confinement to which the rigors of winter condemn the population, which is shut up in narrow houses, generally in overheated air, where the disease-carrying microbes find favorable conditions for development. On the other hand, when the temperature becomes milder, the inhabitants leave their houses to live very much in the open air, and typhoid disappears almost absolutely. Soon, however, under the influence of the heavy rainfalls of the months of July and August, the soil of the cities impregnated with filth exhales miasma, which gives rise to poisoning, manifested under form of fevers, sometimes dangerous, of diarrhœa and dysentery."

Smallpox is the greatest and most deadly scourge of China, the disease always being present to a greater or less extent. This fact is undoubtedly due to the disgustingly filthy sanitary conditions in which the vast majority of the Chinese people live. The three diseases, then, with which an invading army must contend in China are typhoid fever, dysentery, and smallpox. Every care should and doubtless will be taken to ward off and effectually to fight these maladies. It need scarcely be said that one of the most important protective measures to be enforced will be the providing of efficient means of sterilizing water. Another point only second in importance to that just mentioned is the necessity of revaccinating the soldiers and sailors whose duties will call them to the far East. China has not agreed to the Geneva convention, and the Red Cross Society is not represented in its army. The allied forces must be equipped to meet any contingency, as the wounded who may fall into the hands of the Chinese will not receive the care always given them among civilized nations. The disastrous results from an inadequate medical and nursing staff has lately had so striking an object lesson in the South African campaign that there can be no excuse for pleading ignorance in this respect, and if the government of the United States does not profit by the experience so dearly bought by the British, the reckoning at the hands of the American public will surely be a heavy one.

DR. JACOBI ON MEDICAL JOURNALISM.

In common, doubtless, with many of those who have read his address, we can but regret that the American orator at the International Medical Congress in Paris should have chosen as his theme an *apologia pro patria* instead of selecting some scientific subject which he is so well fitted to handle. Had he delivered, as he so easily could, a brilliant address embodying the results of original research or the fruits of his ripe experience, he would have brought much more honor on the country of his adoption than he has by this timid presentation of her claims. But it is not in criticism of the address as a whole that we would write; we desire only to call attention to an insult to a few hard-working members of the medical profession in America and a few business men, of which the author of the address was guilty. In speaking of medical journalism, Dr. Jacobi asserted that "the policy of a

journal, the selection of the advertisements, sometimes even the admission of articles more or less scientific or quackish, is to a greater or lesser extent in the hands of the publisher. It takes an editor of unusual character or prudence either to hold his place or to be removed unceremoniously. But the publisher gets rich; that is what, in his opinion, medical science, art, and quackery are made for." The sentence referring to the editor is obscure, but we take it to mean that the editor must always do as the publisher tells him or be dismissed. If that is what the speaker intended to say, we can only reply that of our personal knowledge it is not true. As to the publishers of medical journals, we have no doubt that they are inspired by a desire to make money, but we believe that other men, even physicians far removed from the corrupting influence of publishers, are not averse to accepting a just compensation for their labor. But that the editor of a reputable journal was ever constrained by its publisher to accept an article which the editor regarded as unfit we do not believe. That the publisher has control of the admission of advertisements is true enough, and natural and proper enough, but a comparison of the advertising pages of the journals owned by lay publishers and those controlled wholly by medical men is by no means to the disadvantage of the former. Dr. Jacobi owes an apology to American medical editors and American medical publishers, for he has recklessly charged the latter with dishonesty and the former with what is no less despicable—a truckling subserviency, and in both cases he has spoken rashly and with insufficient knowledge.

News of the Week.

America as a Field for Post-Graduate Study.—In an address delivered at the opening of the Museums of the Medical Graduates' College and Polyclinic in London recently, Dr. Osler, after dwelling on the importance of post-graduate study, the value of museums as a means of profitable instruction, the desirability of change in one's teachers from time to time, and pointing out the silent revolution that has taken place in the educational field in the United States during the past quarter of a century, suggested to students who wish to have the best the world offers that "the lines of intellectual progress are very strongly toward the West," and made the interesting prediction that in the twentieth century "young English physicians will find their keenest inspiration in the land of the setting sun."

Hot-Weather Mortality Statistics of Philadelphia.—For the week ended August 18th there were reported to the Philadelphia bureau of health 550 deaths—98 more than for the preceding week, and 169 more than for the corresponding week of the previous year. The principal causes of death were as follows: Sunstroke 56, pulmonary tuberculosis 54, cholera infantum 42, heart disease 40, marasmus 27, inanition 24, inflammation of the stomach and bowels 24.

Sir William Stokes, who went out to South Africa some time ago as one of the consulting surgeons to the British forces, died at Durban on August 19th. He was born in Dublin in March, 1839, and received his education at the University of Dublin. He was president of the Pathological Society in 1881, president of the Royal College of Surgeons in Ireland in 1887, and honorary president of the International Medical Congresses at Berlin in 1890, Rome in 1894, Moscow in 1897, and Paris in 1900. He held the office of surgeon in ordinary to the Queen in Ireland.

The British Congress on Tuberculosis.—It is announced in the *British Medical Journal* that a Congress on Tuberculosis will be held in London during the last week of April, under the presidency of the Prince of Wales. Among the vice-presidents are the Duke of Fife, the Marquis of Dufferin, Earl Spencer, Lord James of Hereford, Lord George Hamilton, Lord Reay, Lord Lister, Sir John Burdon Sanderson, Sir Hermann Weber, the presidents of the Royal Colleges of Physicians and Surgeons, the president of the Royal College of Veterinary Surgeons, the director-general of the Medical Department of the Navy, and the chairman of the London County Council. The president of the organizing committee is the Earl of Derby; the chairman, Sir William Broadbent; the honorary treasurers, Lord Avebury and Sir James Blyth; the chairman of the general purposes committee, Professor Clifford Allbutt; and the honorary secretary-general, Mr. Malcolm Morris. The Prince of Wales has consented to open the congress in person. In order to make the congress as comprehensive as possible, every colony and dependency in the empire will be asked to send representatives, and distinguished guests will be invited from Europe, Asia, and America. Authorities in these and other countries will be invited to take an active part in the work of the congress. It is hoped that the congress will be able to adopt practical resolutions which will serve to indicate the measures best adapted for the suppression of tuberculosis. The work of the congress will be divided into sections as follows: Section 1 (state and municipal): president, Right Hon. Sir Herbert Maxwell; secretaries, Dr. Bulstrode, Dr. Arthur Newsholme, Dr. James Niven. Section 2 (pathological, including bacteriology): president, Professor Sims Woodhead; secretaries, Dr. Wethered, Professor Rubert Boyce, Dr. E. J. McWeeney. Section 3 (tuberculosis in animals): president, Sir George Brown; secretaries, Professor Hobday, Royal Veterinary College; Messrs. Harold Sessions, Stuart Stockman (Glasgow), Frank Leigh (Bristol). Section 4 (clinical and therapeutical, including climatology and sanatoria): president, Sir R. Douglas Powell; secretaries, Sir Hugh Beevor, Dr. Hector Mackenzie, Dr. R. W. Philip, Dr. William Calwell (Belfast).

Medical Reciprocity in Canada.—For several years past there has been a movement on foot, initiated, we believe, by Dr. Roddick, of Montreal, looking to the creation of a central medical examining-board for the Dominion of Canada, the object being a uniform standard of medical licensure. Such a

board will not conflict with any of the existing provincial boards or colleges. Under Dr. Roddick's plan a physician possessing a diploma conferring the right to practise in one province of the Dominion may register it with the central board and receive from this board the right to practise in any other part of Canada without further local examination. A similar movement is under consideration in this country, and was the subject of discussion at the meeting of the National Confederation of Medical Examining and Licensing Boards in Atlantic City in June.

The Geneva (N. Y.) City Hospital will receive $10,000 by the will of the late Judge Francis O. Mason. Upon the death of two sisters of the deceased, it will also receive $80,000 additional.

A New Yellow-Fever Serum?—A despatch to the daily papers from Vera Cruz states that the most severe cases of yellow fever there are being treated with Bellinzaghi's serum and seem to improve wonderfully. The patients are quickly relieved of black vomit and revived from their lethargy.

Smallpox has broken out among the Indians on the Turtle Mountain reservation in North Dakota near the Canadian line. There are about twelve hundred Indians on the reservation, and among them were some thirty cases of smallpox, when the outbreak was reported the middle of this month.

Dr. T. M. Lippitt, assistant surgeon U.S.N., who was in charge of the marines sent to Pekin to guard the United States legation there, was wounded in the thigh. The femur was fractured, but the leg was saved, and he is now reported convalescent. He was thought at one time to have been killed.

Dr. Thomas G. Roddick and Sir William Hingston, of Montreal, were among those elected honorary fellows of the Royal College of Surgeons of England at the centenary celebration in July.

The Plague in Manila.—The record of the plague in Manila for the two weeks ending on July 7th, as just reported to the Marine-Hospital service, was seven new cases and five deaths. Of the new cases four were Filipinos and three Chinese.

High Mortality Rate in Porto Rico.—Assistant Surgeon King of the Marine-Hospital service reports that in Ponce City and surrounding country, for the two weeks ending July 28th, there were two hundred and sixteen deaths, against seventy births during the same period. An investigation into this remarkable mortality is being conducted by the superior board of health of the island.

Yellow Fever in Havana.—During July there were thirty deaths from yellow fever in Havana. The average July mortality record for the decade from 1885–94 was thirty-four. The principal unfavorable factor at present is the number of non-immunes. Last year upward of twenty-five thousand immigrants came to Havana, or three times the normal number. The normal death rate from yellow fever, estimated from the statistics of 1885–90, is 4.2 per 1,000. Last year it was only about 1.2 per 1.000. When the enormous increase in the number of non-immunes is taken into account, the rate of mortality for 1899, as well as the rate for July of this year, is much below what might have been expected.

Mortality of Officers and Privates in War.—The official table of casualties in the British army in South Africa shows a curious discrepancy in the relative mortality from disease and that from bullets, of the officers and men. The figures are: Killed in action and died of wounds, 344 officers, 3,183 men. Died of disease, 141 officers, 4,836 men. That is to say, that for every one officer killed in battle nine men die, but for every officer dying of disease thirty-four men die.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 18, 1900. August 11th.—Assistant Surgeon M. K. Elmer commissioned assistant surgeon from July 18, 1900. August 13th.—Surgeon C. H. T. Lowndes commissioned surgeon from June 7, 1900. August 15th.—Assistant Surgeon W. M. Garton detached from the *New York* and ordered to the *Massachusetts* immediately, temporarily, by the commander-in-chief of the North Atlantic Station. August 16th.—Passed Assistant Surgeons C. D. Costigan, G. A. Lung, and J. T. Kennedy ordered to the *Monadnock* for additional duty with regiment of marines. Assistant Surgeon E. Davis ordered to the *Yorktown*. Passed Assistant Surgeon A. R. Alfred ordered to the *Castine*.

Obituary Notes.—Dr. Edwin Evans died at his home in Rome, N. Y., on August 16th, of heart disease, at the age of fifty-five years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1870. He was very prominent in Masonic circles.

Dr. John H. W. Chestnut, of Philadelphia, died at Dutch Harbor, Alaska, on August 5th, of cancer of the stomach. He was born in Philadelphia in 1846, and was a graduate of the medical department of the University of Pennsylvania in 1871.

Dr. Franklin Booth, of Elmhurst, borough of Queens, died at St. John's Hospital, Long Island City, on August 19th, at the age of sixty-three years. The night before his death, while on the way to visit a patient, he was run over by a trolley car and both legs were badly mangled. Before the ambulance arrived he gave directions to one of the passengers how to apply a tourniquet improvised from a bit of rope so as to arrest the hemorrhage. One leg was so badly injured that it was amputated at once; the knee of the other leg was resected after Dr. Booth reached the hospital. He rallied well at first, and it was hoped he might recover, but he soon sank and died about twenty-four hours after the injury was received. Dr. Booth was a graduate of the Bellevue Hospital Medical College in the class of 1864.

Dr. Herbert Park, surgeon on the Red Cross Line steamship *Grangense*, died suddenly at sea on August 11th. He was twenty-three years old, and was born in Wigan, England. He was buried at sea.

Progress of Medical Science.

The Philadelphia Medical Journal, August 18, 1900.

Military Surgery.—W. C. Borden continues the paper on this subject, in which he discusses wounds of bones and other parts caused by bullets of various kinds.

The other original articles in this issue are the opening remarks of the presidents of the sections on tropical medicine, pathology, pharmacology and therapeutics, state medicine, surgery, and army, navy, and ambulance, reprinted from the *British Medical Journal.*

Boston Medical and Surgical Journal, August 16, 1900.

Purgation with Opium.—J. W. Wainwright reports a case of intestinal obstruction, without pain, in a child aged five years, in which high enemata with massage, under chloroform, had absolutely no effect, and operation was thought imperative by the consultants, but objected to by the father, a physician. Another consultant advised the following treatment, which was carried out: A quantity each of tinctura opii deodorata and tinctura belladonnæ was procured, and two drops of the tinctura opii was given on the tongue with a medicine-dropper every half-hour. This was kept up until there was complete coma with stertorous breathing. This condition was maintained for two hours, during which there were contracted pupil, insensible conjunctiva, threatened paralysis of the muscles controlling the tongue, etc. At the expiration of the two hours the patient was allowed to recover from the effects of the drug, taking about four more hours, with the aid of small quantities of tinctura belladonnæ, which had been held as an antidote to the effects of the opium if needed. His first words upon regaining consciousness were to ask for "his chair," when there was a free stool. A knuckle-shaped mass was found, which proved to be cheese. The patient made an uninterrupted recovery. The cathartic action of the opium was rather the complete muscular relaxation which chloroform had not succeeded in bringing about, extending to the muscular coat of the intestines, thus allowing the mass to pass through the ileocæcal valve by gravitation.

The Psychic Factor in Disease.—Robert W. Greenleaf by means of cases elaborates the following propositions: (1) That some cases of illness are simply neuroses without appreciable pathological lesions; (2) that causes capable of producing such neuroses may act while disease is present and should be guarded against; (3) purely psychic causes, as shock, grief, and the like, may pave the way for, if not directly cause, profound pathological disturbance; (4) attention to the psychic is capable, under some conditions, of so turning the scale to health that it may arrest, even perhaps cure, otherwise fatal pathological conditions; (5) attention to the psychic should be considered a routine measure in the treatment of delirium from toxic causes, as alcohol, belladonna, ether, and the like; (6) it should also be considered a routine measure in the treatment and in the prevention of delirium in febrile states, as of typhoid; (7) nurses should be able to enter into psychic relation with their patients; otherwise the value of their services is much lessened and may be harmful.

Surgical Pain.—G. Ryder says that simple, uninfected trauma of the viscera causes comparatively little pain, and this soon subsides. Contractile pain, of which examples are afforded by any abdominal viscus, is typical in its recurrence, and is rhythmical in character. At times it is intense, paroxysmal, and colicky. Inflammatory pain is most severe when due to the colon communis and streptococcus bacilli. Neuralgic pain is paroxysmal, with intermissions, lightning-like and lancinating. Hysterical pain is usually burning and may occupy any part of the abdomen and its contents. Charcot's stigmata will differentiate it from other pains. Obstruction pains of the abdomen come with a sudden onset, are colicky and constant, and cause vomiting. In peritonitis the pain is localized at first, but soon becomes diffused and constant. All abdominal emergencies characterized by inflammation have one common and timely feature, that pain is increased by pressure.

A Brief Report of a Case of Cerebral Abscess of Otitic Origin; Operation; Death.—By George L. Richards.

A Case of Volvulus Complicated by Peritonitis; Operation; Recovery.—By W. P. Giddings.

Journal of the American Medical Ass'n, Aug. 18, 1900.

Therapeutics of Travel and Change of Scene in Nervous and Mental Diseases.—Richard Dewey finds that the dangers of travel predominate over the benefits in the case of neurotic and insane patients, citing cases from practice in support of this view. Travel and change of scene for mental and nervous maladies cannot be judiciously prescribed except by careful consideration of the individual case. Travel may be good in one stage and bad in another of the same disease. If the patient grows worse by travel, this does not prove the treatment bad, for some cases will grow worse whatever is done. It may even be necessary to make a careful experiment before the question can be settled. Another fact regarding travel is that a great deal depends upon the manner of its regulation. Patients who can command every facility for comfort and safety and an experienced medical escort could travel when such a course would be injurious and dangerous for one of moderate means.

Medico-Legal Relations of Opium Inebriety and the Necessity for Legal Recognition.—T. D. Crothers discusses the character of crime committed by the morphinist, showing petty, stealthy criminal acts to predominate. He finds need for the medico-legal study of morphinism. All statements of the opium inebriate should be open to doubt and regarded as worthless so far as the witness-stand is concerned, unless confirmed by other facts and strong circumstantial evidence. Crime is often purposeless. There should be no question of the incapacity of opium-takers to execute bills and contracts. Further study must be made above all theories and based solely on facts and conditions present.

Interstitial Gingivitis from Indigestion Auto-intoxication.—E. S. Talbot discusses the phase of auto-intoxication due to indigestion or disturbance of the gastro-intestinal tract. A factor in auto-intoxication is non-performance of the process of elimination. Another is the formation of toxic products in such quantities as to prevent their destruction by organs like the liver and consequent elimination. People of sedentary habits do not require excessive nitrogenous or starchy diet, and if they receive it auto-intoxication with inflammation of the gum and alveolar process occurs and absorption takes place.

Syphilitic Locolosis Alveolaris.—G. Lenox Curtis discusses under this title pyorrhœa alveolaris, which, he says, is generally regarded as incurable. It is a disease of the peridental membrane aggravated by calcareous deposits with resulting decalcification of the alveolar tissue. The cause of the disease is discussed, and syphilis is found to be a prevalent condition, but one often overlooked. When specific treatment is pushed these patients get well and recurrences are not noted.

Morphinism from the Standpoint of the General Practitioner.—T. J. Happel points out, first, the increase in the consumption of opium, and goes on to discuss how the habit is acquired by patients and physicians. The effects produced upon the child in utero and upon fertility are considered. This vice will have to be faced and fought in the twentieth century as never before. The question of heredity in relation to morphinism is considered.

Neurotic Affections of Interstitial Gingivitis.—J. G. Kiernan says falling of the teeth and similar affections may occur not only from constitutional neuroses, but from disturbances of the cranial and spinal nerves, and after injury to these nerves, epilepsy, neurasthenia, and hysteria.

Treatment of Morphinism.—A. J. Pressey points to the necessity for a more universal knowledge of morphinism, and reports a case. It is not a mere habit, to be broken by the will, and still it is not incurable. The patient is as grateful for relief as are the friends.

The Treatment of Keratoconus with Galvano-Cautery.—By Herman Knapp.

The Surgical Treatment of Conical Cornea.—By Robert Sattler.

The Therapeutic Uses of the Thymus Gland.—By S. Solis-Cohen.

The New York Medical Journal, August, 18, 1900.

Congenital Dislocation of the Shoulder.—John Lincoln Porter relates a case of this condition occurring in a boy. The birth was normal, in head presention, but labor was terminated with the aid of forceps after four hours, because of the haste of the physician to go to another case. The author finds sixteen cases reported in the literature in addition to twelve noted by Scudder in 1890, making with the present one a total of twenty-nine cases. The conclusions at which the author arrives from his study of congenital luxation of the shoulder are: (1) It is of fundamental importance to discriminate between traumatic and developmental cases. (2) The pathology of the congenital cases is not sufficiently known to indicate the most promising line of treatment. (3) Sufficient operations have not been done to establish a successful method of operative treatment or add much to our pathological knowledge. (4) In cases determined to be developmental by the history and measurements, remembering the probable deficiency of development of one or both articular surfaces, an early

operation, before the humeral head has formed a new articular facet under the spine and has itself become deformed, offers the best results.

The Treatment of the Morphine Habit—Can it be Cured?—James H. McBride believes that few people addicted to the use of morphine or opium are permanently cured of the habit. They may be apparently cured, but this is as a rule temporary only. The habit, he says, is but half cured when the use of the drug is stopped, and in order that the cure may be lasting the patient should be under control for months or a year before he is allowed to return to his occupation. The craving for morphine is often strong for a long time after its use has been stopped, and the patient should be under control as long as the desire for the drug continues or until he is strong enough to resist the desire. To treat the morphinist successfully means not only to help him to get rid of the drug habit, but it means to restore if possible a shattered nervous system to a normal condition, and this involves prolonged seclusion and absence of temptation. He advocates institutional treatment under legal restraint.

The Lancet, August 11, 1900.

The Remote Results of Structural Lesions ("Interventions Sanglantes") in Urethrostenosis.—Reginald Harrison sums up as follows a paper read at the thirteenth international congress on August 8th: (1) There is evidence to show that in peri-urethral strictures of the deep urethra the effects of divulsion as practised in Perrève's and Holt's operations may be limited to rupturing the dense stricture bands in the submucosa of the urethra, while the mucous membrane itself escapes any serious injury or laceration and is merely restored by stretching to its original dimensions. Here a permanent cure may result. On the other hand, when the mucous membrane is in itself the seat of stricture and forms part of the latter structurally, it is necessarily torn or lacerated by the process of a sudden divulsion, and the pathological condition consequently becomes assimilated with that of traumatisms of the urethra from external violence accidentally applied which are followed by strictures of the most contractile and recurrent form. (2) There is evidence to indicate that when the entire thickness of a stricture can be included within an incision of moderate dimensions made by an internal urethrotome the normal calibre of the urethra may be completely and permanently restored. When this happens it may be concluded that all the fibres of contraction constituting the stricture were divided at the time of operation; and further, that the converse is equally true. There is also evidence to show that the absence of recurrence under such circumstances is not necessarily dependent on the use of a bougie, though the latter is a precautionary measure which should invariably be advised. (3) In the case of multiple strictures or strictures of the deep urethra of considerable dimensions either in their length or thickness treated by an internal incision of corresponding proportions, apart from other considerations, the tendency to recontraction and recurrence, with an additional amount of cicatricial material, is frequent; the latter being probably due to the circumstances under which healing takes place in wounds of these dimensions so situated. (4) Lesions of the urethra demonstrate in various ways the poisonous effects that unprotected and confined urine is capable of exercising both on the body generally and on the tissues in contact with it, and the liability to such effects is greatly diminished when drainage and irrigation render these conditions of the urine unlikely. (5) In the case of recurring strictures previously treated by incision and in primary strictures of such length or extent as to require an internal section of a corresponding size, or as to which there might be doubt as to whether it would be safely possible so to include them, for the purposes of the operation and its results such wounds should be made with due regard to other surgical principles in addition to the one pertaining to the division of the contraction. (6) There is direct evidence to show that the tendency to recontraction and recurrence of stricture after internal urethrotomy is largely diminished by the concurrent employment of systematic and efficient urine and wound drainage such as the combination of external urethrotomy or perineal puncture affords.

The Indications of Thyrotomy.—Sir Felix Semon says that while in the nature of things thyrotomy can never be an everyday operation, it has in the past been anything but a popular one. The time has now fully come when everybody should be capable of forming an opinion on this question, and if the results obtained be scrutinized with an unbiassed mind he has no doubt that the chief indication for the employment of thyrotomy will in future be found in early intrinsic malignant disease of the larynx.

A New Disease with a Specific Urinary Reaction.—N. F. Surveyor describes a vesicular eruption of the face, in the region of the eye, ear, etc., coming on after a wound of the thumb, some vesicles subsequently appearing near the seat of injury. The urine assumed a bright pinkish-purple color on adding a drop of strong caustic-soda solution to the centrifugalized deposit. This was not due to any drugs taken, as shown by tests. In a record of one hundred and ninety-five urine analyses no such reaction had been previously seen.

The Sympathetic Origin of Post-Enteric Tachycardia.—P. C. Fenwick advances a theory of sympathetic origin of the cardiac phenomena in military convalescents. Cardiac irritability may be due to sympathetic disturbance arising in the superior mesenteric plexus and thence transmitted to the cardiac ganglia and plexus.

On the Prevention of Insanity.—By R. Percy Smith.

Münchener medicinische Wochenschrift, July 31, 1900.

Some Clinical Aspects of the Plague as Observed in Oporto in 1899.—Reiche says that the typical invasion of plague is accompanied by headache, chills, great prostration, and, in many cases, diarrhœa and vomiting. The temperature is high and fluctuating, the abdomen tender, and the spleen enlarged; the bubo is most frequently found in the inguinal region, the axilla being the second site of election. Both sexes are affected with equal frequency; the fever presents nothing characteristic, being either continuous or remittent, and terminating by lysis or crisis. The cerebral symptoms also are of all degrees of severity, varying from the normal to well-marked delirium. The buboes are in nearly all cases the most typical symptom and are usually present from the earliest days of the disease. Sometimes but a single group of glands is affected, but more often secondary involvement in other regions is observed. The size and number of the buboes are very variable, but no conclusions as to the probable clinical course are to be deduced from these factors. In pronounced cases the diagnosis offers no difficulty and may always be confirmed by aspiration and bacteriological examination of the contents of the bubonic abscesses; in mild cases, however, and those in which the glandular manifestations are late in appearing, the true nature of the disease is often long in doubt. It is to be hoped that some serum reaction will be devised to make positive diagnosis possible in the early stages. The therapy includes isolation in clean, well-ventilated rooms and internally tonics and intestinal antiseptics. The value of Calmette's method of injection with Yersin's serum is still *sub judice*.

Experimental Observations on Disinfection of the Hands (Conclusion).—The results of Paul and Sarwey's series of articles may be summed up as follows: (1) Neither of the three mechanical methods of hand sterilization, viz., washing with green soap and brush in hot water, with Schleich's marble soap or Sänger's sand soap is sufficient to effect a satisfactory freedom from germs. On the contrary, even when the cleansing process is continued for some time, the disinfection is still very imperfect, and even hands that have been artificially infected are not to be purified with certainty by these means. (2) It is not possible by purely mechanical means to secure as high a degree of sterilization as is possible by the use of chemicals. (3) Green soap (sapo kalinus vernalis) on account of its high percentage of free alkali is damaging to the skin and not to be recommended for cleansing the hands. (4) From a cosmetic standpoint Schleich's marble soap is very suitable for constant use but it is not yet certain whether it makes an advantageous precursor to chemical disinfection. (5) Sänger's sand-soap is well adapted for habitual use and leaves the skin in good condition for the subsequent action of chemical disinfectants.

The Treatment of Infected Perforating Wounds of the Eyeball.—Glauning recommends highly Eversbusch's procedure of performing paracentesis of the anterior chamber by means of the galvano-cautery. The advantages of this method, as corroborated by the clinical histories of a number of cases cited, are that (1) the infected aqueous humor is allowed to drain away, a continuous flow being possible

much longer through an opening made by the galvano-cautery than through a simple incision the edges of which quickly agglutinate; (2) this is replaced by freshly secreted and not at all or only slightly infectious fluid; (3) through the diminished tension the vascular supply of the organ is greatly favored, and a larger amount of blood rich in the properties needed to combat infection gains access to the damaged area.

A Case of Congenital Hernia Cerebri.—Behm reports the successful cure by operation of a congenital hernia of brain substance. The tumor was situated between the posterior fontanelle and the occipital tuberosity, and was connected with the cranial cavity by its pedicle through a palpable opening in the bony skull. It was of the size of a hen's egg, was fluctuating, non-pulsating, and did not increase in volume when the infant cried. On the tenth day the mass was tied off by multiple ligature and amputated without narcosis. Recovery was uneventful, and six months later the patient was apparently perfectly well and presented only a fluctuating mass of the size of a cherry at the site of the former tumor.

A Case of Spontaneous Intraocular Hemorrhage followed by Rupture of the Globe.—Hauenschild describes an unusual termination for the not uncommon intraocular bleeding. The patient was a woman aged twenty-eight years, whose past history presented nothing of importance except a slight neurotic tendency. On the day of the hemorrhage she experienced only a feeling of lassitude and a slight headache. Suddenly there was a spasm of pain and blood spurted from between the lids of the right eye. Examination of the urine and blood gave negative results.

A Forgotten (?) Heroic Poison Plant of Madagascar.—By Model.

Deutsche medicinische Wochenschrift, August 2, 1900.

Metatraumatic Alimentary Glycosuria.—Haedke took twenty-five patients who had suffered severe traumatism of some sort, either accompanied by injury to the head or involving severe concussion of the entire body such as is produced by falls from a height, and endeavored to establish a causative relationship between the injury and the production of temporary glycosuria. This was done by giving each patient on the day after the accident 100 gm. of pure grape-sugar in watery solution, previous examination having shown the absence of sugar or albumin in the urine. In cases in which chloroform had been given a day was allowed to elapse before the experiment was made. Alcoholism, lead poisoning, etc., were also carefully excluded. The result was that in sixty per cent. of the cases an alimentary glycosuria lasting in some instances as long as a week was produced, and although this observation brings nothing of distinct value in regard to the etiology or therapy of diabetes, still the author considers that it in some sense bridges the gap between simple trauma and post-traumatic diabetes.

The Quantitative Proportions of the Carbohydrates in Diabetic Urine.—Rosin has made a series of observations on the carbohydrates other than glucose present in the urine of diabetics and their quantitative relation to the amount of the latter found. These bodies are mostly hexoses, belonging to the same group as the grape-sugar, and one other, viz., a pentose. By fermentation with yeast it is possible completely to eliminate the glucose and leave the other members of the group behind, and by a further treatment with benzoyl chloride there may be formed from these a series of benzoic-acid esters which possess a definite relationship to the amount of the carbohydrates. By means of this method the author was able to determine that diabetic urine in addition to its charge of grape-sugar contains other carbohydrates in proportions varying from five to thirty times the normal, and, furthermore, that there is no constant ratio between the relative amounts of glucose and the other carbohydrates.

A "Cured" Case of Diabetes Mellitus.—Zaudy reports the case of a diabetic whose sugar excretion at times went as high as 274 gm. to 4,570 c.c. of urine. He was put upon the usual diet and given 1 gm. of salol four times a day. Under this treatment the sugar gradually diminished until after about a month and a half Fehling's reaction gave a constantly negative result, which state of affairs continued even on the patient's return to carbohydrate diet. The general condition was in every way improved and various secondary troubles were greatly relieved. A year after his discharge the patient returned suffering from joint pains. He had been on every-day diet during this time, and it was found that his urine was free from sugar, albumin, and acetone, and was even slightly below normal in quantity. While the author does not deny the possibility of a relapse, he considers the effect of the salol sufficiently remarkable to justify further experiment with its use.

Benzoyl Esters and Carbohydrates in Normal and Diabetic Urine.—By Alfthan.

French Journals.

Parasitic Origin of Eczemas.—L. Brocq presented the first paper in the skin section at the Paris congress, followed by reports by Unna, Jadassohn, and Galloway, and discussed by Kaposi, Sabourand, Neisser, Hallopeau, and others. Inoculations in the dog produced an eruption analogous to that of man and presenting the five histobacteriological symptoms which, according to Unna, are pathognomonic—parakeratosis, formation of serous vesicles with spongy transformation of the Malpighian layer, acanthosis, proliferation of connective-tissue cells of the superior layer of the derma, and the presence of masses of cocci in the serous crusts. A *résumé* of the experiments is presented. Unna finds that among the numerous micro-organisms which have been found in eczema, there are several which when inoculated reproduce eczema. Eczema is contagious, and under certain circumstances epidemic. Galloway says the morococcus described by Unna belongs to the class of organisms giving white cultures but not yet capable of separation from the staphylococcus pyogenes albus. The local infectivity and the chronicity of eczema are chiefly due to the presence of micro-organisms. Kaposi says experimentation shows that eczema may be caused by chemical and physical external agencies. Clinical experience repudiates absolutely the conception of an eczema of parasitic origin.—*La Presse Médicale*, August 7, 1900.

Gastric Ulcerations.—Dieulafoy concludes his paper read in the section of pathology of the Paris congress with a description of the various forms of ulceration of the stomach, from the simple erosion which is the smallest to losses of substance of greater or lesser extent; the simple ulcer being the type of ulcer of chronic evolution with tendency to perforation. Specific ulceration in tuberculosis and syphilis and cancer engrafted upon previous ulcer are conditions discussed. Treatment is, according to the case, medical, specific, or surgical.—*La Presse Médicale*, August 4, 1900.

Hot Air in the Treatment of Affections of the Upper Air Passages.—Lermoyez and Mahu review the question of superheated air as a remedial measure, and give the theory of their procedure with description of apparatus and method of producing and applying the air. It is found useful in congestive spasmodic, vasomotor, and simple chronic coryzas; in subacute tubal catarrhs, otalgia, etc. Contraindications are also given.—*La Presse Médicale*, July 25, 1900.

Chronic Sciatica Cured by a Viper's Bite.—Pommerol relates the curious result of a viper bite upon the heel of a woman who had suffered for five or six years from sciatica. There were shrinking of the tissues of the leg and a limping gait. From the time of the injury all pain disappeared and by degrees a permanent cure of the disability and deformity, etc., took place.—*Gazette des Hôpitaux*, August 2, 1900.

Two Cases of Contusion of the Liver.—A. Gosset relates the history of two injuries from the kick of a horse in which the liver was injured and in which immediate laparotomy was performed, in one instance with success.

Archives of Pediatrics, August, 1900.

Naso-Pharyngeal Disease in Pediatric Practice.—Francis Huber discusses the subject from the side of the specialist as well as from that of the general practitioner. The main functions of the nose are respiratory, olfactory, to give resonance to the voice, and to act as a regulator of the aeration of the middle-ear and of the accessory air chambers in the ethmoidal and sphenoidal bones. Patency and healthy mucous membranes are essential to proper performance of the work. In summing up, the writer says: (1) The removal of the lymphoid hypertrophies in the naso- and oropharynx, with the cure of the associated naso-pharyngeal catarrh, will restore the patency and permeability of the nose. If done early, many local pathological changes may be avoided. (2) The general health will be more or less improved. (3) The mental faculties and general intelligence will be improved. (4) Defects in speech and in hearing due to nasal troubles will disappear. (5) Deafmutism may be relieved. (6) The functions of taste and smell will be restored. (7) Reflex neuroses of various kinds will be modified or cured. (8) Nasal and supposed pulmonary hemorrhages will disappear. (9) Thoracic deformities will be relieved or cured. (10) The tendency to acute rhinitis, pharyngitis, laryngitis, bronchitis, and pneumonia becomes less and less with the restoration of normal respiration. (11) The dangers attending the presence of enlarged cervical lymph nodes will be avoided.

(12) The invasion of various infectious diseases is less likely when the nasal mucous membrane is in a healthy state. (13) The danger of meningeal infection from the naso-pharynx will be lessened. (14) Ear complications in general, and particularly those incidental to the infectious diseases, will be avoided or rendered less dangerous.

Intussusception in an Infant Four Months Old, Relieved by Injection.—Alfred Hand, Jr., relates an instance of intussusception showing the value of opium, which prevented an increase of the intussusception and possibly showed a reducing effect at the start of recurrence. The case illustrated the fact that with reduction the patient is by no means cured, but that the secondary and very likely also the causal primary enteritis is capable of giving rise to many anxious moments.

Three Cases of Head-Nodding and Head-Rotation in Rachitic Infants.—By D. J. Milton Miller.

Perforation of a Tuberculous Lymph Node into the Trachea —Sudden Death.—By A. Caillé.

The Practitioner, August, 1900.

Recent Experimental Contributions to the Pathology of Diabetes.—J. R. Bradford says the fundamental fact in the pathology of diabetes is unquestionably that the blood contains an excess of sugar. Theoretically this may be due to a number of causes: too great ingestion of sugar, excessive formation of sugar, lack of oxidation by the tissues of the amounts of sugar normally ingested or produced. There might, too, be a primary disintegration of the tissues with the formation of sugar. The great bulk of cases at the present time are considered to be either of hepatic or of pancreatic origin. Biedl's experiments are quoted as confirmatory evidence that the pancreas secretes some substance into the lymph stream and so into the circulation, the absence of which is followed by glycosuria. Tuckett's observations are quoted showing that lymph from the thoracic duct when injected into the portal vein will cause glycosuria of varying intensity.

Glycosuria and Diabetes in Relation to Life Assurance.—Hector Mackenzie finds in the growing mortality from diabetes, and the fact that victims are largely from the upper and middle strata of society, a cause for rigid examination for sugar in insurance risks. A case is quoted to illustrate the importance of testing for minute quantities of sugar. Fehling's test with boiling is considered the best. Trustworthy results are obtained from Williamson's modification of Hoffmann and Ultzmann's method. When doubt remains the fermentation test may be applied. True diabetes should always be declined by the company even on short-term policies.

Some Points in the Present-Day Treatment of Diabetes.—The standard diet of von Noorden's clinic, lævulose, phosphate of lime, thyroid extract, uranium nitrate, hepatic extract, antipyrin, boracic acid, spermin, etc., are remedies discussed pro and con.

Clinical Tests for Sugar in the Urine.—By R. T. Williamson.

Heredity and Immunity.—By G. A. Reid.

Norsk Magazin for Lægevidenskaben, July, 1900.

Iodo-Parotiditis.—K. Gron reports the case of a syphilitic patient, who after the administration of potassium iodide had parotiditis eight times out of sixteen. A small dose affected him in some cases, and a large dose in others, but sometimes he took as much as 240 gm. without effect. No other symptoms of iodism were observable, except on one occasion, when he had headache and catarrh of the nasal, pharyngeal, and ocular mucous membranes. The author is unable to explain the phenomena except by the term idiosyncrasy.

The Actual Condition of the Question of Acetone.—H. Chr. Geelmuyden holds that the necessary condition for the production of acetonuria is an insufficient decomposition of hydrocarbons, either from their absence in the diet, or from impaired powers of decomposition on the part of the organism (diabetes). In advanced diabetes acetonuria is a grave symptom, threatening coma. This coma may be delayed by the administration of large doses of sodium bicarbonate. The author discusses the theories which have been advanced in regard to the physiology of the bodies of the acetone series, their origin, seat of formation, etc. It is probable that they are formed in considerable quantity in the organism, to disappear completely later. They doubtless represent links in a continuous series of transformations in which oxybutyric acid-β is the primordial term.

OUR LONDON LETTER.

(From our Special Correspondent.)

IPSWICH—WAR HOSPITALS INQUIRY—HOSPITAL FOR PARALYSIS AND EPILEPSY SCANDAL—SCHOOLS OF TROPICAL MEDICINE—COLLEGE CENTENARY—EMBALMING—POISONOUS "HEADACHE POWDERS"—WEATHER—NATIONAL HOSPITAL SCANDAL—IPSWICH ECHOES—PLAGUE—SALE OF POISONS—WAR HOSPITAL COMMISSION.

London, August 3, 1900.

A goodly number of doctors have put in an appearance at Ipswich, and a considerable proportion have returned already, while more are expected to-morrow. Not a few will make the meeting the starting-point for their holiday. Some went late and left early, others ran down to be ready to read a paper in their section or join in a discussion, and returned the same day. Those of us who remain take a languid interest in the proceedings. All seem elated that the *attentat* of the Council at Exeter Hall was rejected with ignominy, and a few are nervous lest some trick may be played on this last day of the meeting. Of the actual doings you will be fully informed by your own reporters.

The War Hospitals Commission has had some more exciting evidence this week than last, when it was very dull. On Tuesday Mr. Burdett-Coutts was examined, and explained that in using the word "inhumanity" he did not mean to reflect on the medical corps, but on the deficiencies of the supplies. He said no special effort was made to get fresh milk. He said the Royal Army Medical Corps ought to get rid of their rooted objection to female nurses. Perhaps this remark gives the key to his own conduct. We have heard of the "plague of women" in the South African hospitals—not trained and capable nurses, but society-seekers after new excitements. The doctors were hampered in many ways by these meddlesome women who knew nothing of nursing, and when they were excluded they started a campaign of misrepresentation, pretending that the doctors dared not let them see the state of the hospitals. Poor Mr. Coutts seems to have been made a cat's-paw by some of these spiteful society women.

After him, Sir William MacCormac was examined, and repeated what he has already stated as to the hospitals he visited. Lady C. de Crespigny said she saw soldiers lying about outside the tents of the military hospital at Kimberley, and at the Victoria at Bloemfontein food was short.

But on Wednesday more interest was excited, for Rudyard Kipling told the commission that he had got into some hospitals by the back door, pajamas, drugs, etc., at the request of nurses, just to save time and circumvent red-tape. He said that he was told there were drugs in the hospital, but when a man is ill you cannot wait for routine. This seems very well as to pajamas and flannels, but surely it was not for nurses to say what drugs were wanted. Perhaps they were not properly trained nurses.

The distribution of £50,000 of the Hospital Sunday Fund was arranged at the meeting of the Council this week. In consequence of the scandal in connection with the Hospital for the Paralyzed or Epileptic that institution receives no award. The manager, who is dubbed "the secretary-director," appeared before the committee, which invited the board and the staff also to be present. The result of what passed is 'no award," and the public will accept the decision as a condemnation of the board of management. Last year there was ample warning given that the hospital would not receive further award until harmony with the medical staff was restored. This would seem impossible with the present board in office guided by the "secretary-director," and the sooner the governor dismisses the board and appoints men of common sense to manage the hospital, the better it will be for the reputation of the institution and the welfare of the patients. On Saturday *The Times* published a letter signed by the medical staff, demanding an independent inquiry into the administration of the hospital. The revelations that have already been made fully justify this course, and unless the governors take it the scandal will spread, for I hear there is much more to come out, and that of a kind which the public can appreciate, for the welfare and comfort of the patients are involved in the mismanagement alleged to be going on.

Dr. Nocht, port medical officer of Hamburg, and director of the School of Tropical Diseases about to be opened there, has come over to study the methods of the London and Liverpool schools of this department of medicine. Major Ronald Ross, in an interview, said the three schools would work together in the effort to lower the death rate of tropical climates, concerning which England has been too lax. The west coast of Africa may be cited. The great problem there, said Major Ross, is not the Ashantis, but malaria. Do away with that and you have a second India, a

fact recognized by the Liverpool merchants and by Mr. Chamberlain. Malaria germs were discovered twenty years ago, but the discovery has been practically ignored. Germs which may cause dysentery have not been properly studied, and the disease has caused much havoc in South Africa. Major Ross seemed to indorse Professor Wright's discovery of anti-typhoid inoculation, and held that much might have been done to avert the disease in Africa had the method been fully followed. Naturally enough he felt deeply the neglect to follow up the revelations about the mosquito. That malaria is propagated by it, he said, has been proved in India, in Italy, and elsewhere, and the French Academy has recognized the discovery; while England only sends out a couple of expeditions to inquire, instead of taking practical measures on the lines suggested by the discovery.

Continuing the account of the College of Surgeons' centenary celebrations, I may say that some three hundred and fifty persons sat down to the festival dinner on Thursday evening. The Prince of Wales was present, and in returning thanks for the toast of the royal family expressed thanks also that his diploma of honorary fellow would not permit him to practise surgery. Lords Salisbury and Rosebery were equally amazed to find themselves made a part of a College of Surgeons. They might add their influence as honorary fellows to the demands of members for the franchise. On Friday the official reception by the lord mayor and lady mayoress at the Mansion House was followed by a conversazione, which some go so far as to pronounce the pleasantest function of the centenary celebration.

I am told that Professor Renouard is coming over from your side to instruct undertakers and others in the art of embalming. In Europe this is usually done by medical men. But the practice is not general, as I understand it is with you.

A child has been poisoned by a "headache powder" bought at a grocer's. It contained a heavy adult dose of acetanilid. And our legislators permit such poisons to be sold by grocers and stores as freely as carbolic acid and others! Verdict—accident. But what if a doctor accidentally poisoned a patient?

London, August 10, 1900.

The "heat-wave" you sent us was succeeded by cold, rain, thunder storms, and cyclones. Day after day the papers were filled with accounts of floods and other catastrophes caused by the storms, to say nothing of the deaths of men and cattle. The sudden fall of some 30° in the thermometer set men talking about arctic severity, which, of course, was mere exaggeration, for the instrument persistently pointed at temperate. Nevertheless, many were glad to light fires again, although in August. Then came cables saying you were having another heat-wave, and as our clerk of the weather often takes his cue from yours we began to feel that we should yet have some more summer. But here we are still waiting for a share of your heat-wave which does not come, and I write by a fire!

The long-standing dispute at the National Hospital should soon be settled. The staff have signed a letter for publication exposing the breach of faith of the committee and the autocratic conduct of the director. They have further shown the administrative evils of committing all power to one man, and the absurd position of a board which has become the tool of its paid servant. The condemnation by the Sunday Fund committee, which withholds its award this year, should be enough to settle the matter, but the director does not seem disposed to resign. The staff declare they "are unanimous in their resolve to put an end to the evils of the present system." On the appearance of this protest the board called a meeting of the governors for to-morrow. This looks as if they deliberately chose a time when very few are in town, and the staff decline to be a party to anything of the kind and repeat their demand for a full and independent inquiry.

Echoes from Ipswich are loud and persistent. They are jubilant in tone, too, for though the atmosphere of debate was as changeable and stormy as the weather outside, the association scored a triumph over the Council respecting the disgraceful attempt to cheat the members out of their slender rights and grasp the control of the funds. The Council should have understood their position under their "articles of association" when these were framed and the society was incorporated under the Limited Liability Acts. Finding, however, that the apathy of members could be generally counted on, they attempted their *coup d'état* at Exeter Hall, intending to have it ratified at Ipswich. But the scheme was defeated at the outset. No one who looked at it could help seeing that it was an attempt to condone illegality in the past and to hand over every authority to the Council with all the funds, and so erect these would-be despoilers into another petty medical oligarchy. We have too many such "authorities" not to see how they are likely to act, and the Council have only themselves to thank for this disgrace they have reaped from their barefaced attempt.

Dr. Pye-Smith's address seems to have given much satisfaction, judging by the pithy examples brought away and handed round here. Take a sample or two: "To say a man died of apoplexy or paraplegia is to state a fact within the practitioner's knowledge; to say he died of cerebral hemorrhage or of myelitis is only a doubtful inference unless a post-mortem has shown it. A man who believes everything about the action of remedies in Garrod or Wood or in the assertions of advertising druggists is apt to end in unbelief in opium and is sure to be unsuccessful. Is it not a pity to prescribe made-up pills and mixtures of manufacturers, and so lead patients to ascribe their recovery to the special cure instead of our skill? How can statistics be useful when made up of the cases of one disease under curious names? I see many patients suffering from idleness, few from hard work. Worry or nerve prostration is generally only a veil for drink and gambling. Steady work is the best cure for a thousand nervous ailments."

During the discussions warm words were sometimes exchanged, as when the president of the Council said to Mr. Horsley, "Your amendment comes to the same," and was promptly told, "No, it doesn't, and you know it," thus provoking, "Don't question our *bona fides*," and extracting the retort, "The proposal has been shelved the same way before."

When Professor Byers suggested that there was too much centralization in the bestowal of scientific grants, Dr. Saundby was up in a moment, and a lively bit of dialogue ensued. Dr. Haddon joined in and declared much money allowed for grants was really frittered away. He proceeded to remark that he had previously spoken on this subject, and was shouted down with cries of "You have—you have."

Now and then two or three gentlemen were speaking at once with considerable excitement, and that at times they seemed to be passing doubtful compliments, but it was hardly possible to be sure of the words. Nor were these amenities confined to the general meetings. Even the sections were occasionally lively. In one a gentleman disclaimed responsibility for a paper he read for an absent member, when the speaker he had interrupted remarked, "I didn't say anything of you in particular," and was answered, "No, sir; but you shook your fist at me," to the intense amusement of the audience.

The dinner went off successfully—at least those who were present say so, though some who stayed away affect to think nothing of it. The president presided, and here as throughout seems to have given great satisfaction. The toast of the army, navy, and volunteers naturally drew out applause. In responding, Surgeon-General Hamilton referred to the "hysterical allegations of Mr. Burdett-Coutts," and knowing the difficulties of the country declared that it was impossible to imagine more could have been done than was done for the sick and wounded. There was nothing, he said, the field-marshal would not have done to have saved a single man an hour of suffering. When he remarked that the medical service had been for years impressing on the War Office the importance of understanding, some one interrupted with a cry of "They can't," and the remainder of the sentence was drowned in laughter.

Sir John Moore proposed "The Mayor and Town of Ipswich," and the mayor responded in a witty speech provoking much laughter and applause.

Sir C. Dalrymple, in proposing the Association, was not much behind when he admitted he had not heard one of the addresses, but the rapidity of communication in these days was such that he read it in his newspaper in the train before it was delivered.

The president's toast elicited enthusiasm, and was replied to with hearty thanks.

While the dinner was proceeding there was a smoking concert at another place, and in the museum a soirée was given by the ladies of the locality, which was attended by some eight hundred people.

I hear that the garden parties and other out-door entertainments were as successful as the weather permitted. The museums offered shelter in heavy rain to those who fled the sections. The Pathological Museum had some interesting specimens from the Norfolk and Cambridge hospitals, and a series of slides from the London Tropical School illustrating malaria, etc. The drug and apparatus museum was of the usual character—a few novelties attracting attention.

The landing of four cases of plague at the docks caused some trouble to our health department. They were quickly isolated, and the medical officers of health profess to be quite ready to deal with any other cases that may be landed on our coasts.

Another death from headache powders is reported. At last carbolic acid is to be scheduled as a poison. Why not other poisons too?

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-eighth Annual Meeting, Held at Ipswich, July 31, and August 1, 2, and 3, 1900.

(Special Report for the MEDICAL RECORD.)

GENERAL SESSIONS.

(*Continued from page 278.*)

Third Day—Thursday, August 2d.

THE third general session, held in the central hall of the Higher Grade School, was called to order by the president at 2:30 P.M.

Address in Surgery.—MR. FREDERICK TREVES, of London, then delivered the annual address on surgery, taking as his title "The Surgeon in the Nineteenth Century." He began by drawing a picture of England as it was one hundred years ago—the life mostly spent in little villages, when travelling was a luxury limited to the few. London was not one-fourth of its present size; no railway terminus flaunted its structures in the city's midst; there were no telegraph and no telephone. The postal system was without form and void. Education among the mass of the people was a matter of little account, and was to a great extent actually non-existing. As to the surgeon, he was but a sorry element in social life. In the great towns and cities there were esteemed practitioners of surgery who were eminent by reason of their scientific work and their successful practice, but their numbers were few. In the country the surgeon or common practitioner was usually ignorant, illiterate, sordid, not without a suspicion of dishonesty and of a leaning toward the bottle. He was to a large extent a mere retailer of physic, and in the public eye he ranked with the quacks and nostrum sellers with whom he competed. In noting the advances made by the surgeon during the century, the first matter to be dealt with concerned his position as an adviser to his patient. Sick men demanded knowledge from their physicians. In the past the surgeon had to make up by fiction what he lacked in fact. The surgeon of the present day, as an adviser, was in a position which is so greatly improved that it could hardly have been imagined by his forebears of a hundred years ago. He had in the first place to deal with a more enlightened public, and in the second place the additions made to surgical lore had been so substantial that in many departments surgery had reached to the status of an exact science. There was no longer need to call upon invention to fill up the gaps of the unknown. One said that at present nothing was known of the nature and causes of cancer, and the patient was satisfied, whereas at the beginning of the century he should have been told that it was "a diseased hardness" or a "scirrhous degeneration." Doctors still, to be sure, talked of the constitution, of supporting the system, of poverty of blood, diminished vitality, sympathetic inflammation, tonics, galactagogues, alteratives, strengthening the lungs, giving tone to the stomach, etc., but the modern surgeon could dispense with these empty forms. As a man of learning, the surgeon of a century ago knew nothing of the causes of inflammation and of the dangers to open wounds. He had no glimmer of the possibilities of asepsis; he had no anæsthetic, no hypodermic syringe, no clinical thermometer, no practical means of investigation in clinical chemistry. The very name bacteriology did not exist, and the treatment of disease by prepared serums would have seemed to him a wild dream. The microscope played no part in his equipment; he had no laryngoscope nor ophthalmoscope, and his acquaintance with otology, skin affections, and diseases of women was but rudimentary. Conservative surgery and plastic operations were unknown. There was no systematized medical education; the training of the surgeon was paltry, casual, and inefficient. During the nineteenth century, the surgeon, as an operator, passed through a rapid metamorphosis, and had now reached the level of the unexpected. He possessed some qualities which were now falling into abeyance, and which could not pass away quite unregretted. The success of his craft depended largely upon his daring, upon the alertness of his eye, the steadiness of his nerve, and the rapidity of his movements. In spite of moans for mercy the knife had to move on its way steadily, and, undeterred by struggles and bursts of hemorrhage, the blade must needs pass without faltering or sign of hesitancy. At present the surgeon's hand could move with leisurely precision, and the operating theatre had changed from a shambles to a chamber of sleep. The operator had less need for dashing qualities, but he had gained much in the sympathetic handling of his patient. Beyond these general changes in the attitude of the operator there had been special advances in the surgeon's art. Prominent among these might be mentioned: (1) an improved knowledge of anatomy; (2) a readier method of arresting hemorrhage; (3) the employment of anæsthetics; (4) the introduction of antiseptic measures. The science of anatomy was well advanced at the beginning of the century, but it was not taught to the common student. Hemorrhage was expected in operations, tourniquets were employed freely and with harshness, raw surfaces were bathed with styptic solutions which were destructive, or at least opposed, to primary healing. The *écraseur* was employed for the removal of growths of various kinds. At the present day the surgeon had little dread of hemorrhage; bleeding was often anticipated by applying a temporary or permanent ligature to a main artery before a part supplied by that vessel was excised. With an anæsthetized patient, a surgeon could proceed with slowness. Pressure forceps, moreover, had brought a great assurance of security and had done much to extend the area of safe operation. The value of anæsthesia was too well understood to call for comment. It had not only extended surgery, but had engendered surgeons. Antiseptic measures, and the changes wrought by them, were also well known. The surgeon had learned to be clean, and had become aware of the potency of little things. As to the surgeon of the future, the days of the great operator, of the one man to whom all came who could, were rapidly passing away. The practice of pure surgery was now becoming common to the many. The man who excelled conspicuously as an operator would always attain such eminence as his ability deserved, but the exclusiveness of the practice of surgery was quietly vanishing with the century. The change was well. Some undesirable developments there were; men who were not qualified might occasionally perform major operations. We were also in danger of passing from the policy of doing too little to the policy of doing too much. So many were the artificial aids to clinical investigation that it was a question whether the natural acumen of the surgeon would not deteriorate in proportion as he failed to encourage that particular learning which clung to the finger-tips of all great diagnosticians. The skiagraph embodied a substantial gain, but it was to be discounted by the loss of the great element in education which it was slowly replacing. An abdominal swelling was brought under notice. Its features were obscure, but much of the uncertainty of outline could be dissipated by a cultured hand which, with infinite patience and repetition, had learned to construct a reality out of a shadow. It might be said that it was

needless to persist in bringing this much-elaborated means of inquiry to further perfection, since the problem was at once to be solved by an exploratory laparotomy. By such little operation a great advantage was gained, but an opportunity to add to one of the most refined forms of learning was lost. The value of the exploratory incision was beyond question, but among the signs of the times it was impossible not to notice a tendency to resort too readily to this means of solution. There were cases which presented symptoms hard to interpret at any superficial inquiry. Was it worth while in such to undertake an exhaustive critical research and to submit the whole to a trained judgment? The quest would, no doubt, develop habits of observation and powers of weighing evidence; but the process was slow, and an inquiry carried out in a bacteriological laboratory would clear up all doubts, and at the same time dispense with the efforts of a cultured sense. Those, therefore, who were concerned with the education of the surgeon of the future would do well to cherish still this ancient power, and to foster a memory of the fact that surgery was, in its very essence, a handicraft, and that in all that he did the surgeon's great endeavor should be to make his own hands self-sufficing. It was sad to think that this hardly acquired faculty died with the possessor of it. An individual loss did not, however, hinder the general tide of progress. Advance in such a work as ours depended upon the uneventful work of the whole body and was only accentuated by the achievements of the prominent few. The movement was the movement of a multitude in which individuality was, at a distance of time, little to be distinguished, and in which personal eminence contributed a smaller factor than the present was willing to acknowledge. Those who stood forth as the leaders of the advance were merely the elect of the common body and the representatives of a wide intellectual franchise. Even he who startled the world as a discoverer had often done little more than give expression to what was already nascent in the multitude. So as one great surgeon after another dropped out of the ranks his place was rapidly and imperceptibly filled, and the advancing line moved on with still the same solid and unbroken front.

After the usual vote of thanks to the orator the subject of reorganization was resumed. The president of the Council presented one list, and Mr. Horsley presented the other, as had been arranged. The meeting accepted the two lists and appointed the gentlemen named in them the committee, as follows: Nominated by the Council: Surgeon-General Hamilton, South Africa; Mr. J. Cantlie, India and Eastern Archipelago; Sir John William Moore, Ireland; Dr. J. C. McVail, Scotland; Dr. J. Roberts-Thomson, Mr. T. Jenner-Verrall, Dr. S. Woodcock, Dr. R. Saundby, Mr. Andrew Clark, Dr. J. Ward Cousins, Dr. H. Radcliffe Crocker, Mr. H. T. Butlin, England. By Mr. Horsley: Dr. Buist, Dundee; Dr. Byers, North of Ireland; Dr. Gooding, West Indies; Dr. Morier, Australasia; Dr. Bateman, Dr. A. Cox, Dr. Gordon, Dr. Milburn, Dr. Browne-Ritchie, Dr. Whitaker, Mr. Victor Horsley, England; Mr. Edmund Owen, Canada.

Dr. O'Connor said that in accordance with the rules observed in royal commissions the meeting should appoint the chairman, and he therefore proposed Mr. Horsley.

Dr. A. Cox supported this, amid cries of "No, no!" and the president said he must rule the motion out of order, whereupon Dr. O'Connor declared, amid laughter, that the ruling was unconstitutional, and the president provoked renewed laughter by saying, "It is my ruling."

Dr. Sarat Mullick brought forward a motion, of which he had given due notice, on the system of filling professorial chairs in India. These appointments, he said, were given more by virtue of grade rank in the Indian medical service than by special ability of candidates, and he proposed a sub-committee to inquire and report to the council on the subject.

Mr. Horsley seconded. Colonel McLeod and others opposed.

Eventually it was agreed to refer the subject to the parliamentary bills committee.

Mr. R. B. Anderson brought forward a motion of which he had given due notice, condemning the Council for repudiating its subordination to the general meetings, contrary to the articles of association, and, further, his resolutions embodied a plan for securing a change.

The President of the Council rose to order, and said Mr. Horsley's motion was placed in the forefront of the business, by arrangement, for the purpose of dealing with and covering all questions relating to the constitution of the association.

Mr. Anderson said he was not a party to such arrangement, and claimed the right to move his resolution.

The President interposed, and said such had been the general understanding, and he should rule the motion out of order.

Mr. Anderson thereupon gave formal notice of protest against this ruling, and that he reserved all his rights on the question.

A member warmly supported Mr. Anderson, but the president was firm.

It was agreed to pay the expenses of the constitutional committee, and that the provincial members should be allowed a guinea a day for hotel expenses.

Fourth Day—Friday, August 3d.

The closing meeting was called to order by the president at the usual hour.

Address in Obstetrics.—This was delivered by Dr. William J. Smyly, who took for his subject "The Maternal Mortality in Childbirth." He said that the improvement in the death rate did not take place gradually as the light of science slowly dawned upon our art, but occurred suddenly in the seventh decade of the present century. In the Paris Maternity, for example, the mortality dropped in one year from eight per cent. to four per cent. and in 1881 to one per cent., and has since improved, and in all the hospitals of Europe a similar change occurred. As to private practice it was impossible to give any facts founded upon reliable statistics. The statistics of the Rotunda Hospital from 1870–1876 (the period immediately preceding the introduction of antiseptics) gave 8,092 women delivered, of whom 169 died, or 1 in 45.5. During the time from 1890–1896 there were 9,085, with 50 deaths, or 1 in 181.7, a saving of about 200 maternal lives in every 10,000 deliveries. Similar results were shown by hospitals generally. The greatest improvement was noticed in puerperal fever, or septic infection. In the beginning of the century obstetricians were ignorant of the nature of this chief cause of childbed mortality, and were helpless to prevent or to cure it. Epidemics became more frequent and more virulent, and obstetricians endeavored by clinical observation and post-mortem examination to discover its nature; but unfortunately both these roads to knowledge were pursued by the same individuals, and with disastrous results. In 1872 Dr. Churchill reflected the general ignorance when he published in the sixth edition of his well-known work his opinion that puerperal fever was due to mental emotion, cold, putrefaction of portions of retained placenta, gastro-enteric irritation, the state of the atmosphere, epidemic influences, and contagion. With regard to the latter, he felt compelled by the evidence

to admit the possibility of its being conveyed and communicated or excited by those who had attended midwifery cases after being employed in dissection or post-mortem examination, or who were much in contact with fever patients; but in all other cases he attributed its occurrence to epidemic influence. Toward the end of the last century Dr. White, of Manchester, published a remarkable work in which he attributed puerperal fever to the absorption of putrid matter by the lymphatics and vessels of the womb. At this conclusion he arrived by observing the similarity in causation and symptoms in putrefactions occurring in other parts of the body. He further observed that when a putrid wound was cleansed, the symptoms abated. His treatment was therefore directed toward the prevention of putrefaction, and elimination of putrid matter should it have already formed. To these ends he advocated thorough ventilation, cleanliness, and drainage. Free and even cold air should pervade the apartment, and clean linen be supplied every day. The lochia, if permitted to stagnate in the vagina, would soon become putrid, for, he said, it was well known that the mildest humors in the human body, if suffered to stagnate, became acrid as soon as the air had access to them. He therefore encouraged his patients to sit up several times a day, or even to leave their beds so as to prevent a lodging of offending matter in the vagina, uterus, intestines, or bladder. "I must not omit to mention," he said, "the good effects I have experienced from emollient or antiseptic injections into the uterus by means of a large ivory syringe or elastic vegetable bottle in those cases in which the lochia have become acrid or putrid. . . . I have by this means known the fever to be much assuaged and in many cases wholly extinguished." One could not but wonder at White's independence of opinion and the general correctness of his views. Ignorance, prejudice, obstinacy, were the forces against which he combated in vain, and not until fifty years later did another champion take the field against them, to perish in the attempt. This champion was Ignatz Philipp Semmelweis. In 1846 he, a young man of twenty-eight years, was appointed assistant to Professor Klein in the maternity department of the Vienna Hospital. His observant mind was struck by the fact that the mortality in childbed was immensely greater in the department attended by students who also attended post-mortems, than in the department reserved for pupil midwives. He concluded that the cause of puerperal fever must be an infection from without, due to the transportation of poison by the fingers and instruments of attendants, and by ordering disinfection of hands, instruments, and air, he reduced the mortality from 5.3 per cent. to 1.27 per cent. Jealousy and unbelief thwarted him in Vienna and in Buda-Pesth, and he retired from practice to write a work on "The Nature and Prophylaxis of Puerperal Infection." In his endeavors to impress upon others the importance of his life-saving truths he fretted and fumed his life away, and finally died in an insane asylum, of septic infection. Had he had more patience he might have observed that the seed he was sowing had taken root. His views were adopted by Michaelis, Lange, and Simpson, and Pasteur's wonderful discoveries set them upon a firm scientific footing. Lister in 1864 astonished the world by the wonders of antiseptic surgery. Stadfeld, Bischoff, Fritsch, Schroeder, Breisky, and Lucas Championnière were the pioneers in the movement for applying antiseptic principles to obstetric practice. Soon the spray was replaced by the douche, and the vagina was douched with antiseptic fluids before and after every labor; the uterus was soon included in the process. Accidents and deaths occurred, however, due to the injection of air and fluids into the veins. Leopold showed that by thoroughly disinfecting the external parts and avoiding unnecessary examinations better results were obtainable than by prophylactic douching. The whole question of the value of prophylactic douching resolved itself into the probability or even possibility of auto-infection. That the vaginal discharges often contained germs, many of which were apparently aseptic or saprophytic, was undeniable, but were these germs really dangerous to the patient, and could they be removed by antiseptic measures? These were the two important questions. Krönig injected cultures of various bacilli into the vagina, and found that they were all eliminated within twenty-four hours. In cases in which, after injecting the micro-organisms, he at once thoroughly scrubbed out the vagina with a one-per-cent. solution of corrosive sublimate or lysol, they had not entirely disappeared at the end of thirty-six hours. The douche, therefore, not only failed to dislodge them, but so altered or removed the natural discharges that for at least twelve hours the normal bactericidal action of the vagina was annihilated. The speaker believed that unless nurses could be trusted to preserve perfect asepsis, vaginal prophylactic douching was productive of more harm than good The teaching of Semmelweis and Sir James Simpson, that infection was carried chiefly by the hands of attendants, was now the generally accepted opinion. Experience proved that an absolutely aseptic condition of the hands could not be insured by any known process, and from this is learned: (1) to avoid as far as possible septic contamination; (2) to spare no pains to render the hands as innocuous as possible; (3) to restrict local interference within the narrowest bounds. The last of these rules included not only unnecessary operative interference, but also needless vaginal examinations. Next to antiseptics, the author considered the substitution of external for internal examinations the most important advance in modern midwifery. By whom it was introduced he did not know, but its systematization and popularity were owed to Pinard, Credé, and Leopold. By its means it can be ascertained whether the woman is pregnant, the period of pregnancy, the position and presentation of the fœtus, whether it was living, dying, or dead, and whether there was one child or more in the uterus. The presence, course, and progress of labor could be told; and pelvic deformity and many other conditions could be diagnosed. External examination was safer, gave more information to the examiner, and was easier and more reliable. In the Rotunda Hospital, students made more mistakes with the vaginal than with the abdominal method. Two things could be made out only by vaginal examination—the condition of the os uteri, and a prolapse of the umbilical cord. A fat or rigid abdomen on the part of the patient also necessitated an internal examination. The speaker seldom examined more than once in the course of a normal labor, and then as soon as possible after full dilatation of the os, as indicated by a rupture of the membranes or a change in the character of the labor pains. Disinfection of the hands should be thorough. In the treatment of the disease when once established, local disinfection by antiseptic douching, the curette, abdominal section, and ablation of the infected organs had all been employed with success. The general treatment with which he had met most success was that introduced by Runge in 1886, and consisted in cool bathing, nourishing diet, avoidance of internal antipyretics, and free administration of alcohol.

A vote of thanks was moved by Professor Byers, who particularly alluded to the address as one full of information, and full of another quality which he regretted was so rare, viz., the effacement of self.

The motion was seconded by Dr. Griffith and carried unanimously.

Afterward votes of thanks were unanimously passed to the mayor of Ipswich and a number of others who had contributed to the success of the meeting, concluding with one to Dr. Elliston, the president, which was suitably acknowledged, and thus the annual meeting came to an end.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

First Day—Wednesday, August 1st.

President's Address.—Dr. W. S. A. Griffith, of London, in the course of a brief introduction, said that the subject chosen to-day for discussion had never been discussed before, and that there was no subject more thorny; the subject chosen for the second discussion, viz., uterine fibroids, was one about which there were very different opinions held, and the reason that the subject of the treatment of post-partum hemorrhage was chosen for the third discussion was that, although it was so well worn, yet letters frequently appeared in the medical papers asking for guidance as to the best method, and it was felt that some authoritative pronouncement would do good.

Puerperal Fever in Relation to Notification.—Dr. Berry Hart, of Edinburgh, opened the discussion on this subject. He said that notification of scarlet fever and typhoid was accepted as desirable by all, but that there were difficulties in the way of the general acceptance of the notification of puerperal fever. Statistics showed that the mortality of puerperal fever was not diminishing. The evident objections to notification were: First, the difficulty of defining what was puerperal fever; second, the risk of misleading statistics; third, the reluctance of the practitioner to notify. With regard to the first, he would define puerperal fever as any form of puerperal septicæmia. By septicæmia he understood an acute disease from the entrance of organisms through the genital tract; these pathogenic organisms spread along the lymphatics to the body, and it was this spread which marked the disease as notifiable. The case had usually to be diagnosed on clinical conditions. He recognized (1) an acute rapid form; (2) the ordinary lymphatic form; (3) the rare venous form. The second form was the usual one, and under this head would be included cases of sapræmia. The third variety taxed the practitioner's skill most. It originated in the infection of a uterine clot inside the uterus, and the infection passed along the blood channels. These cases were the most tedious, trying, and difficult to diagnose. Serum reaction now eliminated typhoid. He considered that the origin of puerperal fever from drain poison was not proven. Some of the rashes of septicæmia closely resembled scarlet fever, and before the diagnosis of the latter disease was accepted its source should be clearly proven. Notification was not necessary in localized pelvic inflammation, nor in gonorrhœal cases, nor cases of that rare disease, puerperal tetanus. Gonorrhœal inflammation may come on late in the puerperium, and gonococci will be found in the discharge. With reference to the unwillingness to notify, he found that it was not so general as would be supposed. He found on examining the statistics of many large towns that the notifications considerably exceeded the deaths. In regard to prevention, he thought that the most important point was the correct management of the third stage. The advantages of notification were: (1) that it showed the frequency of occurrence—this was not diminishing; (2) that it would help in prevention by putting the medical officer of health on the track of dangerous midwives. The municipality should provide hospital accommodation for these cases, as they required special local treatment and most careful nursing. He was not optimistic with regard to the treatment of bad cases. Notification would also improve our knowledge of the disease. The literature of the subject was principally represented by Boxall, Allingworth, Olshausen, and Naumann.

Dr. Smyly, of Dublin, spoke of the great importance of obtaining statistics of the mortality in private practice. It was impossible to obtain that until a record was got of all the deaths occurring after childbirth, whatever the cause. The returns of the registrar-general divided deaths after childbirth into three classes: (1) Cases of metria; (2) deaths due to causes directly dependent on the labor; (3) deaths due to causes not connected with labor. Under the latter head were many cases certified as pneumonia, scarlet fever, etc., which were really puerperal. He deplored the perpetuation of the term puerperal fever. He referred to the difficulty of determining what should be notifiable. Dr. Berry Hart said: "Notify systemic infection but not local inflammations." The speaker would ask, why not? For scientific purposes notification would not be of much use, but it would be useful for saving life. It damaged a man's practice to use the word puerperal fever, and he would like to see some other name adopted.

Dr. Campbell, of Belfast, said that there were two great sources of puerperal fever: (1) the midwife; (2) the patient. He believed in auto-infection as from gonorrhœa. A great advantage of notification would be that there would then be supervision of midwives. It would increase public interest in the training of midwives, and improve the quality of monthly nurses, raising them more to the level of surgical nurses.

Dr. Boxall, of London, had investigated the statistics of the mortality from childbirth up to the end of 1898, and found that since the publication of his previous investigations in 1894 the returns showed no improvement. In 1880 the registrar-general instituted a system of inquiry into all cases returned under doubtful headings such as peritonitis, and the proceeding had raised the mortality of puerperal fever by one-twelfth. Statistics showed a serious state of affairs. We now knew that puerperal fever is a preventable disease. In lying-in hospitals the mortality was formerly fearful. Now puerperal fever was practically abolished; even when septic cases had been brought in from outside the spread of the disease could be absolutely prevented. Mere tabulation could do no good, and he did not think that it was necessary to remove these patients to an isolation hospital. He doubted previous auto-infection of the patient as a cause, giving as his reason that if that were so there would be more cases in strictly conducted lying-in hospitals than did arise, and he agreed with Dr. Smyly that all serious cases of illness should be notified. He would not attempt a definition of what was puerperal fever.

Dr. Macan, of Dublin, was entirely opposed to notification. He advised that a practitioner should refuse to attend cases unless a nurse was employed of whose knowledge of asepsis he felt assured.

Professor Byers, of Belfast, approved of notification. It would enable the physician to see where the disease was, and to find its cause, and in the end would lead to prevention. We must not oppose it because it might injure the practitioner; that was an unscientific and selfish position to take up. There was great difficulty in definition. We must accept fever after delivery, face the facts, and boldly say that it must be notified. He advocated bacteriological examination of the discharges, and disbelieved in auto-infection. He would teach students and midwives to make as few vaginal examinations as possible.

Dr. Brummet, of South Australia, said that the law in that country provided for the notification not only

of puerperal fever but also of phlegmasia dolens, cellulitis, etc. He pointed out the difficulty in notifying when there was a rise of temperature which might turn out to be temporary.

Dr. Targett, of London, said that recently at Guy's Hospital three beds in an isolation ward had been set apart for cases of puerperal fever which might arise in the out-door maternity. The cases admitted had done so remarkably well as to show that there would be an advantage in isolation hospitals.

Dr. Helme, of Manchester, strongly opposed the teaching that the doctor was always responsible. The public were already too much disposed to take that view, and this constituted one of the chief difficulties in notification.

The President drew attention to the absolute difference between the notification of puerperal fever and that of other infectious diseases. No one blamed the doctor for the occurrence of smallpox or scarlet fever, but in connection with puerperal fever the man, be he consultant or general practitioner, always suffered. That, however, should not stand in the way of his telling the plain truth, as the alternative of deliberate concealment entailed far worse results. In the speaker's opinion, when a regular temperature record was kept it was shown that all severe cases began within twenty-four hours.

Dr. Berry Hart, in reply, said that some seemed to think that if they kept their hands clean that was all that was required, but he thought the management of the third stage of labor was equally important, and was of opinion that the Credé method had done much harm through leading to premature and hasty interference with the normal mechanism.

On the motion of Dr. Boxall the following resolution was carried *nem. con.*: "That it be a recommendation to the council of the association, that in the opinion of this meeting it is desirable that the notification of puerperal fever (septicæmia) should be adopted generally."

Cephalotripsy for the After-coming Head.—Dr. Targett, of London, read a paper with this title. In the case recorded the conjugate diameter was two and three-fourths inches. Cæsarean section was refused. The head was perforated behind the ear. One blade of the cephalotribe was passed through the hole made by the perforator and the other blade applied over the face, and the head was easily delivered. Attention was particularly drawn to this method of applying the instrument.

A Human Placentation in its Second Stage.—Dr. Catharine von Tussenbrock, of Amsterdam, read this paper. This embodied a series of prolonged microscopical examinations of the placental structures, which were illustrated by diagrams, and among other things she proved that at the sixth month the reflexa had perished by simple necrosis due to pressure of the growing ovum.

Second Day—Thursday, August 2d.

Natural History of Fibroids and Recent Improvements in their Treatment.—Mr. Alban Doran, of London, opened the discussion, saying that we did not know the pathological relation of fibroids to the ovaries nor were we certain of the precise significance of menorrhagia in certain cases. The growth of these tumors was very variable and the prognosis as to growth extremely uncertain. As a rule, they got smaller at the menopause, but there were many exceptions. As regarded treatment, most of them required no operative treatment. He would put aside broad-ligament fibroids in an entirely separate class. They always tended to grow to a large size, and should always be removed. They seldom caused enlargement of the uterus, but the uterus was thin and flattened out over the growth, and the operation for their removal differed from any form of hysterectomy, and these tumors should not be included in statistics of hysterectomy. In the operation for fibroid of the broad ligament the risk of hemorrhage was greater, that of septicæmia less. Fibroids of the uterus were really myomata composed of plain muscular fibre, and ergot acted on the latter, but he thought that the action of the ergot depended rather on the fact that the tumor was uterine than on the fact that it consisted of muscular fibre. Heart disease was a contraindication to the use of ergot. No definite change was ever detected in the ovaries connected with fibroids, that would account for the growth of the fibroid. Removal of the ovaries in uncertain cases checked bleeding. On the whole, oöphorectomy was not followed by satisfactory results, and when failure occurred one could never be certain that the entire ovary had been removed, as ovarian tissue was sometimes found extending along the ovarian ligament right up to the uterine wall. Oöphorectomy was practically discarded. It was difficult to be clear as to the nature of the hemorrhage observed in fibroids; in subserous ones there was no hemorrhage whatever. The distinction between menorrhagia and metrorrhagia was not easily determined. There was no rule as to prognosis of rate of growth. Slow spontaneous disappearance might occur; rapid disappearance was doubtful, and he thought cases recorded under the latter had been instances of error in diagnosis. Abdominal measurements were useless for determining the growth of the tumor unless the skin was stretched by the growth, and the sound fallacious. The menopause was deferred. It was very difficult to be assured that hemorrhage was not menstrual. The majority of fibroids ceased to trouble after the menopause. The usual indication for operation was bleeding. He drew attention to the close connection which had been shown to exist between fibroids and heart disease. An improvement in expectant treatment had been the introduction of chloride of calcium and salines. Simple fibroids producing no symptoms could often be extirpated easily, but this was not surgery. If operation was decided on, then the following were the latest methods: (1) The serre-nœud was still allowed to be used in cases of fibroids complicating labor or pregnancy, when speed in the operation was desirable. (2) Myomectomy. (3) Pan-hysterectomy. (4) Retroperitoneal hysterectomy. This latter was the more popular method in the country; there was, however, a danger in the sutures which were left in the cervix. As regarded the removal of the ovaries, it had been shown that removal of the uterus led to atrophy of the ovaries, and his own experience was that removal of the ovaries was not essential. He thought retroperitoneal hysterectomy was the best operation.

Dr. Berry Hart, of Edinburgh, thought that if conservative opinion was founded on experience of the clamp operation, it was not to be relied on. The effect of the menopause was not always so favorable as was generally stated. The two great improvements in operation were: (1) The arrest of hemorrhage by ligature of arteries, not on the tissue of the cervix; (2) the Trendelenburg position.

Dr. Smyly, of Dublin, thought it very difficult to advise. For himself in the past he thought that he had operated too little rather than too much. There was now very little difference between pan-hysterectomy and the subperitoneal method. Personally he adopted Doyen's method of operation and found it best.

Mr. Harrison Cripps, of London, said the question of operation depended on (1) What is the fatality if left alone? (2) What is the fatality of operation?

It was very difficult to make a statement as to the first question. Champneys had shown from the post-mortem records of St. Bartholomew's that in eighteen hundred cases of women at the fibroid age one hundred and forty had fibroids, and that among the number death was directly attributable to the fibroid in three cases. In his opinion the three greatest improvements in operation were: (1) Improved antiseptic methods; (2) intraperitoneal treatment of the pedicle; (3) the Trendelenburg position. As regarded antisepsi a noticeable improvement at "Barts" had followed the introduction of the use of a solution of biniodide of mercury in spirit, 1:500, for the sterilization of the hands.

Dr. Macan, of Dublin, pointed out that a very large number of fibroid tumors were never suspected, and consequently did not enter into any statistics.

Dr. Cameron, of Toronto, estimated that fifty per cent. of negro women had fibroids. He agreed that it was impossible to prognose the course of a fibroid. He adopted Kelly's method. One could avoid ligature by using forcipressure. A pressure of two thousand pounds could be obtained.

Dr. Roger Williams, of Bristol, said that statistics showed that not more than one in two thousand women died from fibroid. There were no statistics available on which to estimate the frequency of fibroids. Some foreign observers had said that twenty per cent. of women had them. He calculated that there were one million women in the United Kingdom suffering from fibroids.

Dr. Stanmore Bishop, of Manchester, thought medical treatment of fibroids absolutely useless, but did not think that any surgeon would recommend removal of every fibroid. He thought that the two great improvements in their removal were the abandonment of the extraperitoneal clamp operation and of the drainage tube.

Dr. Campbell, of Belfast, had regretted advising non-interference. He had found that chloride of calcium and hydrastis had a good effect in checking hemorrhage. He had a good opinion of vaginal hysterectomy for small multiple fibroids giving rise to serious hemorrhage. He favored pan-hysterectomy in preference to retroperitoneal, as the latter left the cervix with its blood supply partially cut off.

Dr. Macnaughton Jones, of London, had seen women with fibroids become lunatics, and also die from uræmia, sloughing, or heart disease. In all cases in which fibroids were producing any symptoms he advised hysterectomy.

Dr. Stanley Boyd, of London, asked what was the effect of the salpingitis which so frequently accompanied fibroids on the production of hemorrhage. She said that the only way of estimating the growth of fibroids was by careful bimanual examination both per vaginam and per rectum. She asked if atrophy of the ovaries which followed hysterectomy had the same effect on the woman as removal of the ovaries by operation. It was sometimes difficult, when the fibroid grew low down in the uterus, to avoid leaving some of the uterus in doing the retro-peritoneal operation.

Dr. Scharlieb, of London, pointed out that in cases in which a fibroid became frequently incarcerated in the pelvis, of which she gave an instance, removal was needed; and in these and similar cases the question of operation should be fairly put before the patient. Since the serre-nœud was abolished Champneys' seventeen per cent. mortality, which was based on that operation, was fallacious. She thought it important not to introduce any chemical antiseptic into the peritoneal cavity. She had removed a fibroid tumor by myomectomy from a girl fifteen years of age. She thought that the results, both immediate and remote, were better if the ovaries were left in doing hysterectomy. She never used the elastic ligature or transfixed the stump with a ligature.

Dr. Giles, of London, said he had no faith in drugs or electricity. He agreed that it was better to leave the ovaries.

Dr. Briggs, of Liverpool, would add to the indications for operation injury to the fibroid from mechanical violence, of which he gave an instance.

Dr. Skene Keith, of London, had known only one case in which a fibroid had grown after the menopause. He would put the date of the latter in bleeding fibroids at the age of fifty-two to fifty-four. He believed in, and practised, Apostoli's method.

The President said that all were agreed that in serious conditions one should operate. Cases on the borderland were the difficult ones in which to decide. No means existed of estimating the mortality of fibroids, but hospital records showed that it was not high. The question of operative interference could not be settled by discussion, but must be left to individual discretion. He agreed with the general tendency of the discussion. It was exceptional for a fibroid not to cause menorrhagia, and very rare for it to be associated with amenorrhœa. The large majority of fibroids ceased to cause any trouble after the menopause. To say that medical treatment did no good was gross exaggeration. He would ask how many women were kept in comfort for years by rest at the periods and drugs. He believed in chloride of calcium, combined with iron, in anæmic cases.

Mr. Doran, in reply, protested against the idea that operation should be advised because complications might ensue which would kill the patient later. In some of the older cases in which diseased appendages were removed by oöphorectomy, the good result which followed was due to the fact that the symptoms depended on the salpingitis and not on the fibroid. He had used the Trendelenburg position, but twice with stout patients he had had difficulty with the anæsthetic with the patient in that position.

Vaginal Hysterectomy, its Immediate and Remote Results.—Dr. Scharlieb, of London, read a paper with this title. She gave details of forty-six cases; in thirty-five of these the operation was done for malignant growth. In these thirty-five cases four patients died within a month, one from kidney disease, one from shock, and two from sepsis. These were all the deaths in the whole forty-six cases. Of the thirty-five cases of cancer seventeen patients were now alive and free from recurrence. The known recurrence had been seven per cent. The average age of the patients was forty-seven years.

Vaginal Enucleation versus Vaginal Hysterectomy in the Treatment of Some Fibroids of the Uterus, with Notes of Cases.—Dr. Briggs, of Liverpool, read this paper. The largest fibroid removed by this method weighed four pounds ten ounces. He pointed out how much better vaginal operations were borne than abdominal operations.

Third Day—Friday, August 3d.

Post-Partum Hemorrhage, its Prevention and Treatment.—Dr. Byers, of Belfast, opened the discussion in the unavoidable absence of Dr. Dakin, of London. He said that with respect to the definition of post-partum hemorrhage one could not fix the amount of blood lost. Some had said one pound of blood and upward should be considered to be post-partum hemorrhage, but patients varied, and one must judge by the constitutional effect produced and by the presence of relaxation of the uterus. One of two pathological conditions was present in cases of hemorrhage: (1) open vessels in the placental area—uterine atony; (2) a wound of the parturient tract. He would

discuss to-day particularly the first. One of the predisposing causes was hemorrhage in previous labors; this was important especially in the poor, when pregnancy had occurred too frequently. In the well-to-do, want of exercise, too much food, and alcohol were predisposing causes. Other clearer causes were over-distention of the uterus, albuminuria, and extreme mental depression. He had seen some severe cases in which the patient had been depressed owing to death of the husband during the pregnancy. During delivery predisposing conditions were any condition of high vascular excitement attended with a pulse of over 100, and sharp, quick, inefficient pains in the second stage. With regard to chloroform he did not believe that it caused hemorrhage except through the hurry and inefficient attention to the third stage, which were frequently associated with its use. As to prophylaxis, in every case one should never deliver in the absence of pains. Forceps were very dangerous in cases of secondary uterine inertia. In the management of the third stage the conditions must be understood; the nature of the natural separation of the placenta must be studied. It was bad management to squeeze it off the uterine wall, but the uterus must be followed down as the child is born and the hands kept on the uterus, never letting it go. The woman should be turned on her back as soon as the child was born, and then one should wait until the placenta was separated, twenty minutes or longer. One could tell when the placenta was separated by the fundus uteri rising and the lower segment appearing distended on abdominal inspection, and resembling the distended bladder. He made a practice of tying the second ligature on the cord just at the vulva, and then one would readily see when the cord descended still farther. As soon as it was clear that the placenta was separated, with the next pain one should gently squeeze out the placenta. He did not believe in pads, saucers, or books on the abdomen. In cases in which there had been previous post-partum hemorrhage he advised slow extraction, and rupture of the membranes early in labor. For the treatment of actual hemorrhage he advised (1) uterine massage; (2) the injection of hot water. He spoke strongly against putting any mercurial preparation in the water. It was not good practice to introduce the hand unless one felt sure from an examination of the placenta and membranes that a portion was left behind. He discountenanced iron, but spoke strongly in favor of plugging the uterus by Dührssen's method, which he regarded as very useful. The bimanual method he considered to be tedious and, as it involved the introduction of the hand, dangerous, and he would rather pack. If packing failed it should be withdrawn, followed by douching and repacking. If that failed Schauta had advised forcible inversion of the uterus and the tying of a piece of gauze round its neck, leaving it on for six hours. In one case he had arrested the hemorrhage by forcibly drawing down the uterus with a vulsellum. Hemorrhage from wounds in the parturient canal had been described as hemorrhage from a contracted uterus. The diagnosis was made, in the case of wound of the vulva, by inspection; if the wound was in the cervix the bleeding would go on in spite of contraction of the uterus, and if a Bozeman's catheter was used to wash out, blood would be seen in the uterine stream. The treatment of the wound was, in the vulva, ligature; in the vagina or cervix, ligature or packing. The treatment of the anæmia following hemorrhage consisted in: (1) Keeping quiet; (2) saline injections, which were of the greatest advantage (he infused underneath the breast); (3) strychnine injections hypodermically; (4) feeding.

Dr. Boxall, of London, said that he would consider the amount of blood to be lost to make a case one of post-partum hemorrhage as upward of twenty ounces, but of course much depended on the individual, and a better standard would be the weight of the blood lost compared with the weight of the patient's body. Some cases of hemorrhage were due to the retention of a clot the result of an ante-partum hemorrhage. In the General Lying-in Hospital, London, out of ten hundred and fifty-eight cases there was a loss of twenty ounces or more in ninety-four patients, and in twenty of these there was undue retention of placenta or membranes; in eight an ante-partum clot had formed. Auvard had described what he called the "collarette" placenta as a cause of hemorrhage; this consisted in a circular reduplication of the chorion, usually at the edge of the placenta, and at this reduplication the chorion was rotten and easily gave way; in the Lying-in Hospital this year out of two hundred and ninety patients twenty-two lost twenty ounces of blood or more, and of these fifteen were found to have a collarette placenta. He found that women addicted to alcohol were very prone to have post-partum hemorrhage. He believed in early rupture of the membranes as a preventive. The forceps would ward off hemorrhage if judiciously applied so as to save the uterus from becoming tired, but in many cases the forceps, from being used injudiciously and to save the time of the practitioner, produced hemorrhage.

Mr. Stanmore Bishop, of Manchester, advocated compression of the abdominal aorta so as to stop the hemorrhage while the uterus was resting and recovering contractile power.

Dr. Scharlieb, of London, had worked for some time in India, and had found post-partum hemorrhage frequent among European women there and found that the administration of quinine during pregnancy was in those cases a prophylactic.

Dr. Campbell, of Belfast, had found drawing down the uterus with a vulsellum useful, and used hot water through a flushing curette.

Dr. Smyly, of Dublin, said the uterus might be relaxed and no hemorrhage take place; in that case it should be left alone. He had found this especially the case after using chloroform.

Dr. Briggs, of Liverpool, also approved of pulling down the uterus with a vulsellum. This proceeding gave aid in plugging, and by its means the use of a very large amount of gauze was avoided.

The President said that the uterus must be emptied. It was a difficult thing in practice to be sure that all membrane was removed. He disapproved of the introduction of the hand into the uterus. He always managed the third stage with the patient on her back, and found it easier to detect lacerations of the perineum in this position. As regarded anæsthetics, he believed that chloroform interfered with uterine contraction; ergot had an opposite effect, and he had made a practice of giving a dose of ergot before administering chloroform. For plugging the uterus when no gauze was at hand he advised clean linen rags soaked in some spirits.

Dr. Byers made a brief reply, in which he said that he was glad to find that there was so general an agreement with the lines of treatment that he had laid down.

Conservative Surgery of the Tubes and Ovaries. — Dr. Stanley Boyd, of London, read a paper on this subject. She gave an account of twenty-two cases with one death; in ten there was recurrence of inflammatory symptoms, and in three further operation became necessary: in six there was a good result, and in three pregnancy followed the operation. She found that a better result was obtained from this kind of operation on the ovary than on the tube.

Dr. Scharlieb found that operating in gonorrhœal cases was of very little good while active inflammation was still going on.

The President would emphasize the danger of

gonorrhœa in women, especially with reference to the marriage of men who were suffering from that disease in a latent form. If part of an ovary was removed when pus was present there was always a danger of further trouble.

An Account of a Case of Complete Inversion of the Uterus of Three Years' Duration.—Dr. Parslow, of Birmingham, read this paper. The case resisted all efforts at reduction, and amputation was performed. The uterus was split from front to back, opening the peritoneal cavity, and the broad ligaments were transfixed and tied before amputation of the uterus. The author believed that this method of transfixing and tying the broad ligaments had not been described before.

This concluded the business of the section.

SECTION OF SURGERY.

Second Day—Thursday, August 2d.

Discussion on Fractures.—Mr. W. H. Bennett, of London, read a paper on the methods at present in use in the treatment of simple fractures. In order to obtain information on the methods of treatment usually adopted by surgeons who were in the habit of seeing a large number of simple fractures, Mr. Bennett had sent out to some three hundred hospital, infirmary, and colliery surgeons in Great Britain a list of questions as follows: (1) What is the method you usually adopt in the treatment of fractures of the bones of the extremities? (2) Do you use massage or passive movements; if so, at what period after the receipt of the injury do you adopt either or both of these? (3) What is about the average time which elapses in your practice after the occurrence of the injury before the patient is allowed to resume his ordinary calling, in simple fracture? (4) Have you had experience of the immediate treatment of simple fractures by wiring, screwing, etc.? If so, what is your opinion of the method, especially with regard to the scope of its application and to the risks entailed by its use, and its results? (5) Assuming that you treat the majority, or at all events some, of your cases of fracture of the patella or olecranon by wiring, screwing, etc., what treatment do you use in cases which you do not treat by operation? (6) In cases of fracture of the patella treated by wiring, when do you commence passive movement at the knee, and how long is it, as a rule, before the patients can return to their ordinary callings with free movement at the joints? (7) In cases of fracture of the patella treated by immediate suture, have you any experience of results which are defective, as partial stiffness of the knee, complete stiffness, or suppuration? (8) Have you had experience of the treatment of fractures by the immediate use of massage and passive movement? If so, what is your opinion?

The answers received respectively may be briefly summarized as follows:

(1) The treatment adopted by nearly half the surgeons in question (forty-seven per cent.) was the application of removable splints, and plaster of Paris was not used at any period throughout. Several practitioners stated that they had given up plaster of Paris on account of the slow recovery following its use. Plaster of Paris or other fixed arrangements were more used in the Provinces and in Scotland than in London. Twenty-six per cent. used removable splints first and plaster of Paris later. Twenty-two per cent. advocated the use of plaster of Paris from the first.

(2) Sixty-three per cent. used passive movement without massage; twenty-five per cent. used both; twelve per cent. neither. In London sixty per cent. of those who used passive movement at all reserved passive movement with or without massage to those cases in which joints were involved in the injury. Out of London eighty per cent. of the surgeons followed this course. The periods at which passive movement was started varied largely. Thus in London thirty-five per cent. used it from the first, twenty-six per cent. after firm union; while in the country only thirteen per cent. used it from the first, and, speaking generally, the time at which it was started was later than in London. But in Edinburgh and Glasgow, like London, the practice of early passive movement seemed followed.

(3) From a comparison in detail of the answers given to question No. 2, and the returns given to this question, it followed that the quickest recoveries occurred in cases in which movements active and passive were earliest used. Thus in fracture of the femur, in London fifty per cent. returned to their calling in less than twelve weeks; in the provinces only twenty-five per cent. In London six weeks was the usual time lost by a patient for simple fracture of both leg bones, in the country eight.

(4) In answer to question No. 4, half those who replied had had experience of the operative treatment, and half had not. Of those who had, only five per cent. expressed unqualified approval; thirty per cent. operated in a few special cases, as spiral and oblique fractures of the tibia; sixty-five per cent. entirely disapproved unless the case was absolutely unmanageable without.

(5) In answer to question No. 5, when wiring of the patella was not done owing to the fragments being in apposition or nearly so, the age or health of the patient, or because the surgeon was opposed to the operation, twenty-five per cent. used fixation by splints with arrangements of strapping; seventeen per cent. used removable splints of wood, leather, poroplastic felt, etc., giving facilities for early passive movement; sixteen per cent. fixation by splints plus elastic traction, fifteen per cent. immediate use of plaster of Paris, eight per cent. the inclined plane, five per cent. Malgaigne's hooks, two per cent. Thomas' knee splints. Of the total number sending returns six per cent. aspirated effused blood. The majority of those who operated did not do so at once, but in from three to twenty-one days. In the case of the olecranon the majority were adverse to operation, and the favorite treatment was splinting in the extended position.

(6) After wiring the patella, in London twelve per cent. commenced passive movement at once, fifteen per cent. in seven days, fifteen per cent. in fourteen days, twenty per cent. in twenty-one days; the average time before patients were ready to resume work was eight weeks. In the provinces the figures indicated that passive movement was begun later, and the average time before patients were ready to resume work was nine weeks.

(7) As to the adverse results in operations on fractured patellæ, one hundred and eleven surgeons sent replies. Twenty-eight had experienced suppuration; in eight cases amputation had been necessary. Three others had had fatal results. Twelve had experienced stiffness with material disability. In five the wire had cut through the bone during attempts at restoring movement.

(8) In answer to question No. 8, only forty replies were received. Of these thirty-three surgeons had had personal experience of it, and thirty-one were in favor of the treatment.

Mr. Bennett's own experience was against screws or ivory pegs as a means of fixing fragments. He preferred wire, but even wire sometimes acted as an irritating foreign body. Of course operations were open to the general objection that they were not suited to the general body of practitioners unless great care was taken in maintaining asepsis. He thought that the

disability following fracture was rather due to the matting of parts, and not to the bad union. It was astonishing how often sailors with very badly united fractures were seen in whom no serious incapacity followed. He, therefore, advocated early and methodical passive movements to prevent matting and fixation. The sooner the joints above and below the fracture moved, the sooner would the patient recover. Of course the bones should be kept in position as much as possible, but moderate displacement, if not rotatory, need not necessarily impair the use of the part. No one method could be insisted on for all cases. The value of the operative treatment must be restricted to certain cases, and operations on the patella were not so free from risk as had been thought.

Mr. Margle thought systematic investigation as to the exact time at which union did take place was needed. He felt sure he had seen a humerus firmly united in three weeks. He had wired the patella as a routine practice and never saw any harm come of it. That surgeons had neglected the value of manipulations in the past, the records of the successes of bone-setters clearly showed.

Mr. Keetley thought the paper had a slight tendency to make one underestimate the value of getting the bones back into their exact position. Care must be taken in drawing inferences as to the times given. Patients were notoriously given to prolonging the period of convalescence for "compensation" reasons. The three points that interested him were pinning, wiring, and massage. Pinning he considered most valuable for fracture of a diaphysis not easily kept in position. He used rectangular or L-shaped pins, inserted some distance from the fracture (otherwise they would not hold). The one arm of the pin being inserted into the one fragment, and the corresponding arm of the other pin into the other fragment—the fracture having first been carefully reduced—the free arms of the pins were made to overlap and were lashed together (so that two L's became a U). Wood-wool pads and bandages were all that was needful. He believed he had seen a femur unite in two weeks. For fractures near joints, *e.g.*, a condyle, or the head of the fibula no mode of treatment other than wiring would answer at all. A distinction should be definitely made between active movement and massage. What harm could result from two weeks' rest? And he could see no advantage in disturbance earlier.

Mr. Robert Jones disagreed with both Mr. Keetley and the president, Mr. Marsh. He believed union took much longer than either of them stated, in fact longer than the text-books stated. He believed the so-called "ambulatory" treatment, *i.e.*, keeping the parts in place by apparatus and letting the patient get about before union was firm, must result in shortening. Some years ago he had been in the habit of measuring all fractured femurs when the patients were discharged from the infirmary as cured, and then measuring them again after the patients had been about some time. He generally found some further shortening on the second measurement. This he took to mean that the bones, although united, were not firmly enough knit to stand the constant thud of walking, but were driven in together in some degree. If there was one place he would not operate, it would be in fractures of the condyles into the elbow-joint. It was a very serious matter to make a compound fracture of the elbow-joint. And these cases, if put up in the flexed position to make sure that flexion would not be lost, did remarkably well. In Colles' fracture the want of thorough reduction was the trouble, not the length of time the bones were kept fixed. As to wiring the patella he had been unfortunate. He had done twelve cases, and one of these patients, in whose case the joint was supposed not to have been opened, died. Another came back at a later date with abscess from the wire causing irritation.

Mr. Eve said that he had operated on four cases of fractured leg bones for various reasons since October last. He thought wiring the patella was an operation which rested with the conscience of the surgeon. If he could be sure of asepsis the procedure was ideal, and could be pressed on the patient because the functional results were better. Passive movement should be commenced in about two weeks. He agreed with other speakers that screws were useless, and very liable to break away. In many cases of Pott's fracture the malposition of the bones was the cause of the trouble, and adhesions were not. He had recently operated on one such case, and found a fragment of bone displaced between the tibia and fibula, which explained the difficulty experienced in keeping the foot in position. He did not approve of early passive movement, because adhesions were not likely to be formed under seven to ten days.

Mr. Jonathan Hutchinson, Jr., advocated wiring the patella plus open operation because any blood clot present in the joint could be removed. It was most important to get absolute bony union, and only wiring could obtain that. He doubted if massage and galvanism could prevent wasting of the quadriceps, and was sceptical as to the value of early and immediate massage. In injuries around the elbow joint fixation should be adopted for three weeks, after accurate replacement had been made; then slight active movements should follow. Massage used early for fracture of the surgical neck of the humerus would probably cause non-union. Too much must not be claimed for it; it might even cause compound fracture.

Mr. F. F. Burghard advocated immediate operation in every case of fractured patella, and used no splint from the first, only cotton wool and a bandage. In three weeks' time a splint was put on, and the patient allowed to get up. In Pott's and Colles' fractures he thought massage was useful. The less splinting was used the better. If any fracture could not be reduced, or kept reduced, it should be cut down on and wired. He believed matting of muscles had a lot to do with the ill results met with. Screws held only for a few hours, and speedily caused softening. He used wire whenever possible.

Mr. Bennett, in reply, denied being an enthusiast for massage. He said his object was rather to elicit information than to lay down any views of his own.

Removal of Large Vesical Calculi.—Mr. H. S. Burton read a paper on the removal of large stones from the bladder. He gave the notes of a case in which he removed by suprapubic lithotomy a stone weighing ten ounces five drachms. The patient lived for four months and then died from pyelitis. The operations at one's disposal for dealing with large stones were reviewed, and the main points of the suprapubic operation, litholapaxy, and median and lateral perineal lithotrity were discussed. He himself advocated the suprapubic operation, because the bladder could be opened freely and thoroughly explored, and stones of any size removed. The only disadvantage he saw was that the wound left might be long in healing.

Mr. P. Freyer had done a large number of operations for stone, chiefly in India, and strongly advocated Bigelow's method in all possible cases. Whenever that operation could be done, it was immensely superior to any other. In his last four hundred cases he had adopted cutting operations only thirteen times. The difficulty was, what to do with large stones. What was a large stone? He should say one of two ounces or over in an adult. The mortality of the suprapubic operation was very high, probably fifty per cent. He should say a cutting operation should be selected if

stricture was present and the stone large, in some cases of enlarged prostate if the bladder was so contracted that sufficient antiseptic solution could not be introduced to enable litholapaxy to be safely done, or if the stone was so hard that the instrument failed to crush it. He showed his specially-made giant lithotrites for dealing with large stones, and maintained that in proportion as he had abandoned cutting operations so had his results improved.

Mr. Cadge believed that if general surgeons ventured to deal with such large stones as the specimens shown by Mr. Freyer, by Bigelow's method, disaster was sure to follow. He thought Mr. Freyer had had too much success. He meant that litholapaxy was an operation requiring much practice, especially in dealing with large stones, and that because one surgeon had acquired great dexterity in doing these cases, all must not be encouraged thereby to expect such good results. He could remember Sir Henry Thomson's advocacy of the suprapubic operation as the cutting method against any other. But in these days perineal lithotrity had not been introduced. He took it that the question was narrowed to a comparison between the suprapubic operation and the various forms of perineal lithotrity. Experts would do just the operation they felt competent to do, but it did not follow that such operation was most suitable for the average surgeon. The suprapubic method was easy of execution, although too much stress must not be laid on the ease with which it could be done. No vessels of any size could be cut, or hemorrhage would follow; the parts could be easily seen, and the bladder digitally exposed in every part. The advantage was manifest if the stone was encysted or fixed. What could be said against it? The mortality, and the fact that ready and complete healing did not always follow. But the technique and details had not yet been altogether settled, and as time went on much improvement in the mortality and general results might be expected. As far as he could see, there was no one particular danger to which it was liable. The alternatives were perineal lithotrity, median or lateral, and combined with the use of giant lithotrites as in India, and by Mr. Milton, of Cairo, or Mr. Harrison's method. In the first place no comparison was to be made between Indian, and he presumed Egyptian, practice and English. Eastern natives were notoriously tolerant of major operations, and the stones met with were much softer. He did not believe that even one of Mr. Freyer's giant lithotrites would crush a six- or eight-ounce East Anglian pure uric-acid stone. Many of theirs in Norfolk were uric acid, not friable urates. He had warped instruments made by the best London makers in cases which the stones were only one and a half ounces in weight. He thought Milton's and Harrison's methods liable to give rise to much laceration. His conclusion was that for the generality of surgeons the suprapubic method was safer for large stones.

Professor Nicolaygow, of Christiania, said he had failed in attempting to crush a hard stone by the lateral perineal method, and had had to do a suprapubic. He thought it was easy of execution, and very safe if done "*à deux temps*," the bladder being opened after adhesion had taken place.

Mr. Reginald Harrison's experience of perineal lithotrity was not large, but it had been successful. The reasons for its adoption had been large stones or complications. Milton and himself had done fifty cases with only one death. He had no objection to the suprapubic method *per se*; but he had seen recurrent stone fixed to the hard cicatrix left after that operation.

Mr. Keegan confined his remarks to cases of very large stones. In these he would select perineal lithotrity, because the mortality of the suprapubic was fifty per cent. In India the natives died of the suprapubic operation the same as here. Their mortality had been 42.17 per cent. That of the median and lateral perineal methods was much less.

Mr. Chicken referred to a case in which, although symptoms of stone were present in a lady, no stone could be felt by sounding. He dilated the urethra and digitally examined the bladder, felt a stone encysted, and extracted it per urethram. It weighed 810 grams. No incontinence of urine followed.

Mr. Freyer pointed out, in reply, that it was interesting to hear from Mr. Keegan's statistics that natives of India did sometimes die after operations. Some people seemed to believe that in India operations were so pleasant and free from risk that the natives underwent them merely to while away the monotony of existence. Did these people believe that the genito-urinary tract of the Indian had been rendered so aseptic by the constant imbibition of the pure water from the Himalayas or the sacred fluid from the Ganges that operations could be undertaken on his bladder with impunity? Anyhow, that had not been his happy experience.

Third Day—Friday, August 3d.

Roentgen-Ray Methods.—Dr. J. Mackenzie Davidson read a paper and gave a demonstration on recent progress in the use of the Roentgen-ray methods in surgery. He illustrated how misleading the use of the rays might be as ordinarily used, if proper precaution was not taken, since the picture was a shadow picture and liable as all shadows to distortion. To obviate this he devised the method of taking two photographs, with the tubes 6 cm. apart, and then viewing the two photographs in a Wheatstone's stereoscope. The distance thus chosen was about the distance between the centres of the two pupils. Thus, suppose an observer wished to locate a bullet in a leg, and suppose him looking at the leg from a distance of two feet. If he were gifted with Roentgen-ray vision, he would see the bullet in three different positions with regard to the leg bones, accordingly as he looked with the right eye, left eye, or both together. But binocular vision would give him the most accurate information. Dr. Davidson then would take a point two feet away, representing the observer's nose, move the tube 3 cm. to one side, then 3 cm. to the other, and take an *x*-ray photograph in each case. By combining the two thus obtained in Wheatstone's stereoscope very accurate localization could be obtained.

Open Incision for Club-Foot.—Dr. A. M. Phelps, of New York, read a paper on "The Open Incision for Club-Foot; its Indications and Abuses." He said that in 1878 he did his first operation by open incision on a case of relapsed club-foot. From then until 1897 he operated in five hundred and thirty-eight cases. Altogether up to the presen the had operated in some sixteen hundred and fifty cases. He maintained that the mortality was *nil;* that any foot at any age could be straightened; that the results were better than by other methods of operation, and that relapses were rare. These good effects were obtained in a few weeks, and the weight of the body kept the foot in good position afterward. In America tenotomies and the use of retention apparatus were being largely abandoned. The means at the surgeon's disposal in dealing with club-foot (varus) were, according to the severity of the case: (1) Manual manipulation; (2) subcutaneous tenotomy; (3) open incision (Phelps' operation); (4) open incision plus linear osteotomy of the neck of the astragalus; (5) same as the preceding (4) plus removal of a V-shaped piece of os calcis; (6) amputation. In the infant, aged from three to

four months, mature experience enabled him to present a method which should cover all operative procedures for club-foot. The soft parts caused the chief trouble, and, that being so, were we justified in such an operation as osteotomy or tarsectomy with a mortality of five per cent.? No. On the other hand, Dr. Phelps spoke vigorously and emphatically against the prolonged use of orthopedic instruments and appliances and traction. His plan was, excluding all those cases in which manual reposition was possible, to cut all the contracted parts that offered resistance to replacement, beginning with the tendo Achillis, and going as deep and as far as the peroneus longus tendon. The cut must be at right angles to the long axis of the foot. The operator should not cease his efforts until the foot was over-corrected, going on if needful to linear osteotomy of the neck of the astragalus and wedge osteotomy of the os calcis. Of course the operation should be antiseptically performed, and perhaps Esmarch's bandage should be used. Older patients should be treated in the same way, age itself being no bar to the operation. The only exceptions should be those cases in which the foot could be manually replaced, or those curable by tenotomy only. In dressing, the organization of the blood clot in the wound, or filling with chipped catgut, helped to abridge the healing-process. Plaster of Paris was the only retention apparatus he used, with in some cases hooks in the bandage and lacing to keep the foot in position. The cases would need looking after for months and years. Of his first one hundred and sixty-one cases six per cent. relapsed; since then relapses had been rare. His conclusions were that all feet at any age after four months, with shortened skin and ligament, should be operated on by the open method, and that club-foot shoes of every name and nature should be discarded.

Mr. Jackson Clarke, while thanking Dr. Phelps for his paper, felt that he must dissent from him from every point of view. What were the results of his early cases? Unless these patients were seen in adult life, no idea at all could be formed as to the value of the proceeding, and unless they had been thus watched figures as to relapses were valueless. He himself years ago had gone in for this type of procedure, and very thoroughly, but had now entirely given it up. He mentioned cases of double varus in which one foot had been operated on by Dr. Phelps' method, the other by tenotomies as in the older method. That done by the open incision failed, the tenotomized foot, however, being satisfactory. Young club-feet should be guided in growth, not mutilated. If it went abroad to the medical world that a big operation was needed in these cases, many thousands of feet would be ruined. He had no fault at all to find with the older methods. He was quite satisfied with Mr. Adams' results, and his treatment was based on the least possible surgical interference. Most cases required nothing more than division of the tendo Achillis, and then the wearing of a simple inside upright and guiding strap. As to Dr. Phelps' denunciation of apparatus, did he not himself explain his method of hooks and lacing and plaster of Paris? And this was quite right too. A judicious surgeon ought to use all the possible means at his disposal for his patient's benefit. He believed much of the present unfortunate state of affairs, that is, the resorting to large operations on these feet, was due to the much too general ignorance of orthopedics and of the results of orthopedic methods of treatment.

Mr. A. H. Tubby was especially pleased to have heard from Dr. Phelps exactly his method of procedure. Mr. Tubby had thought the operation consisted in the division of the soft parts only on the inner side of the foot—at all events, that was the description accepted up to now. But now he heard from Dr. Phelps that he went on to bony operations as well. He quite agreed with the remarks of the last speaker, and he believed the operation to be a bad surgical procedure. The result looked well on the table, but did not stand the test of time. It stood to reason that in a large gap, like that formed in this operation, a scar must develop. That scar would contract and an incurable varus result. His own feeling was that he preferred to be driven into such open operations, and not to take them up voluntarily. Dr. Phelps' operation of open division of soft tissues he condemned from his own experience. As to the modification of that operation by bone division also he had no personal knowledge. Dr. Phelps had said the operation was often indicated at four months of age. He had never yet seen a foot at this age which required any operation of the kind. On the other hand, he had seen many bad results of such procedure. He should say that no open operation was ever needed before the fourth or, more often, sixth year. All these methods were designed to shorten the time taken in treatment. Did they do so in the end? If they did, which was doubtful, the results by the older, slower methods conscientiously carried out were far superior. Then after the open operation one has burnt one's boats, and if the result was not satisfactory nothing further could be undertaken. But in fairness to Dr. Phelps it must be acknowledged that the originator of any operative procedure in all probability had a better idea of the nature, scope, and limitations of his method than had his copiers; and therefore he would do the operation better than they. So that instead of finally and absolutely condemning the open method from the results seen in England, he would rather hold judgment in suspense until he had paid a visit to America and seen Dr. Phelps' own cases.

Mr. Noble Smith thought that the points in discussion so far resolved themselves into matters of degree rather than divergence of principle. Dr. Phelps himself says he would exclude all cases curable by manipulation and tenotomy. If that were so few would be left for open methods. Of course we had not seen Dr. Phelps' cases, but we had seen many done by excellent surgeons, and many relapses among those. And the successful cases, or those exhibited as such at the various societies, certainly showed much want of elasticity. He showed casts taken of a bad case of varus in early infancy, and at intervals up to adult life, and maintained that the case showed that bad cases of varus were perfectly curable by tenotomies and the usual orthopedic methods.

A member said that at the City Orthopedic Hospital they were most anxious to do Phelps' operation, and that for the last seven years he had been looking for cases suitable for it. Unfortunately he had been unable to find them, the cases they saw there being perfectly curable by less heroic measures. Dr. Phelps' method was certainly fascinating in its simplicity, and in the description of its results. The older methods were prolonged in carrying out, and liable to relapse. But was the open operation not liable to relapse? Perhaps it would be maintained that the very many undoubted relapses they saw after Dr. Phelps' method had not been properly done. But could it be believed for a moment that the many good surgeons who did these cases undertook operations for which they were incompetent, and about which they were ignorant? He did not for a moment believe so. The operation, not the surgeon, was at fault. Then if it became generally accepted in the profession that such treatment, apparently so simple, as Dr. Phelps described was the proper course to follow, they would certainly see many feet hopelessly ruined by surgeons attempting the operation who were quite ignorant of

the harm that might result. For example they recently had had a case brought in of a foot irrevocably spoiled, in which the house surgeon of one of the general hospitals in London had on his own responsibility done a Phelps operation, badly perhaps, but certainly needlessly. He believed that everything possible should be tried before resorting to the operation.

Dr. Phelps, in reply, did not agree about want of elasticity in feet after his operation. He maintained that the very cases on which his paper was based were those which had been treated for years by the older methods, and treated unsuccessfully. As to Mr. Smith's casts he did not consider the result perfect; the tarsal arch was not normal. He believed the relapses seen so often in London were due to the surgeon's not going on far enough, but stopping before over-correction was obtained. The failure to divide the deltoid ligament led to relapses in many cases. How could a contracted skin or the deep ligaments be dealt with except by his method? As to the scar contracting, experience had shown that such did not occur. Rather than many thousand feet being ruined by the adoption of his teachings, he believed that if his method was not adopted many thousand more patients would go to their graves uncured. As to the older methods he had come to the conclusion that they were unsatisfactory, after years of careful study. For fifteen consecutive years he had visited Europe. He had seen Mr. Adams' work and cases, and also the result of continental surgeons; and it was on their failures that his views as to the inefficiency of the older orthopedic methods were based.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 18, 1900:

	Cases.	Deaths.
Tuberculosis	181	154
Typhoid fever	50	12
Scarlet fever	47	2
Measles	51	6
Diphtheria	172	33
Laryngeal diphtheria (croup)	3	
Cerebro-spinal meningitis	0	6
Chicken-pox	5	
Smallpox	1	

Treatment of Malaria in the Roman Campagna.—A campaign against malaria in the Agro Romano was undertaken at the beginning of this summer by the bureau of hygiene of Rome. Instructions were issued to the resident physicians and special medical officers were despatched by the bureau to patrol the Campagna, distributing quinine tablets and impressing upon the farm laborers and superintendents the urgent necessity of observing certain simple prophylactic measures. From a translation of the official instructions issued by the bureau (published in *The Lancet* of July 7, 1900) we take the following directions for treatment in developed cases:

"*Primary Attacks.*—The administration of quinine in tablets, each containing ½ gm. (gr. viiss.) of the sulphate should be recommended during the subsidence or at the end of the febrile attack. The quantity administered should be 2 gm. daily for three successive days and 1 gm. daily for other four days. Tabloids sufficient for a week's treatment are to be given in a small box with appropriate directions to each patient. After the remedy has been suspended for five days, it will be well to follow the directions for relapsing cases, even although there be no return of the fever. Hypodermic injections are to be employed only in exceptional cases. The medical officer is recommended to supervise the treatment of primary æstival infections in which the fever of the first attacks should be suppressed as far as possible, experience having proved the importance of prophylaxis of early treatment.

"*Relapsing Fevers.*—The administration of sulphate of quinine should be carried out as follows: After the last febrile attack, or during its decline, 2 gm. of the quinine in four tabloids are to be given. The following day, the same doses are repeated. During the next five days 1 gm. of sulphate of quinine in two tabloids is administered, after which the treatment is to be suspended for a week. The following week the administration is to be resumed, the patient being supplied with the same quantity of quinine as in the first week, and the quantity taken regulated as before. When the fever no longer returns, the daily dose should be reduced by one-half. The administration is then to be again suspended for a week. In the fifth week the same amount is to be given in the same way as in the third week, and so also during the seventh week. As a rule, it is not necessary to continue the administration beyond the seventh week. During the weeks in which the quinine is suspended, he may, if he thinks proper, administer 'Bacelli's mixture'[1] or capsules and tabloids containing iron. For convenience of reference the above rules may be stated in the following tabular form:

Tables for the Administration of Quinine.

A—In Primary Malarial Fevers.

(Tabloids of 50 cgm.)

	Tabloids.	Total.
First day (near end of febrile attack)	4	2 gm.
Second day	4	2 "
Third day	4	2 "
Fourth day	2	1* "
Fifth day	2	1 "
Sixth day	2	1 "
Seventh day	2	1 "

"Suspend the administration for five days, then continue as in Table B.

B—In Relapsing Malarial Fevers.

	Tabloids.	Total.
First day (at end of febrile attack)	4	2 gm.
Second day	4	2 "
Third day	4	2 "
Fourth day	2	1* "
Fifth day	2	1 "
Sixth day	2	1 "
Seventh day	2	1 "

Second week.—Suspend quinine; daily observations, etc. (in anæmic persons five tablespoonfuls of "Bacelli's mixture").

Third week.—Repeat treatment as in first week, but if no return of fever reduce dose by one-half.

Fourth week.—Suspend quinine; daily observations (in anæmic cases four tablespoonfuls of "Bacelli's mixture").

Fifth week.—Repeat treatment as in third week, with the same precaution.

Sixth week.—Suspend quinine; observations (in anæmic cases four tablespoonfuls of "Bacelli's mixture").

Seventh week.—Repeat treatment as in fifth week. End of treatment if no return of fever.

* If on the fourth day after commencing treatment the fever does not disappear continue with doses of 2 gm. In exceptional cases use hypodermic injections.

"The treatment of the fever, whether primary or secondary, should be commenced according to the scheme laid down, even when the last attack has occurred some days previously. Whenever the fever asserts itself it is best to recommence the treatment as for the first day and to continue according to the rules prescribed. The

[1] "Bacelli's mixture" contains the following ingredients: sulphate of quinine, 3 gm.; tartaric acid, 3 gm.; arseniate of sodium, 5 cgm.; distilled water, 300 gm. The dose for an adult is one tablespoonful.

total dose of quinine should be given within two hours, *i.e.*, at intervals of half-hour, three-quarters of an hour, or one hour, according to the fractions. A glass of water should, if possible, be drunk after every tabloid, acidulated by preference with lemon or vinegar. In children the doses should be reduced in proportion to age.

"*Hypodermic and Intravenous Injections.*—Hypodermic injections are reserved for cases of intolerance of quinine by the stomach and for cases of pernicious fever. In these cases two hypodermic injections are made, each of 1 gm. of the bi-hydrochlorate of quinine dissolved in 5 gm. of distilled and sterilized water. A large syringe is employed, the lateral regions of the abdomen being chosen and the skin washed with gauze and absolute alcohol. The needle should also be sterilized with absolute alcohol or by boiling in a test tube. The hypodermic solution in sterilized vials, each containing 1 gm. of bi-hydrochlorate, will be supplied to the medical officer. The patient must then be conveyed to the temporary hospital or to the city. In the hospital injections of camphorated oil and caffeine will be made. During the two subsequent days 2 gm. of quinine must be given daily either by injection or by the mouth (one tabloid of ½ gm. every hour). The intravenous injections according to Bacelli's method will be made in extreme cases in the sanitary station hospital. For these injections boiled solutions of neutral hydrochlorate of quinine at a temperature of 40° C. should be employed exclusively in doses of 1 gm. in 10 c.c. of chloride of sodium solution (0.75 per cent.)."

Psychology of Crazes.—Professor Patrick, writing on this subject in *Appleton's Magazine*, says: "If we turn to the behavior of the normal adult man in mental epidemics and crazes of all kinds, from the crusades to the massacre of St. Bartholomew, from the tulip mania in Holland to the Dewey welcome in New York City, we observe that his behavior is to some extent similar to that of the hypnotic subject and the child and the primitive man. The general character of mental action in epidemics is as follows: Men become imitative beings, and their actions are determined by suggestion from the action of others. Memory and the association of ideas are inactive, and there is an inability to reason and an indisposition toward deliberation and calm reflection. Past experiences are disregarded, remote consequences are not seen, and behavior is repulsive and spasmodic. Feeling is very strong, and every kind of emotion is apt to be exaggerated. Calm observation is also lacking, and mental images may be mistaken for objective reality, as in the case of the hallucinations that are frequent in these phenomena."

Mr. Watson Cheyne on Nursing at the Front in South Africa.—In the course of a long letter to the London *Times*, describing his experiences as consulting surgeon to the army in South Africa, Mr. Watson Cheyne alludes to the question of nursing. He "strongly agrees" that female nurses are better, "especially for cases of typhoid fever," than males. Admitting that women could not go forward with an advancing army, and deprecating their employment in field hospitals, he holds that female nurses must be limited to base hospitals. Mr. Cheyne proceeds: "As a matter of fact in this campaign a much larger number of female nurses than is arranged for in the army regulations was employed. My belief is that a still larger number might have been used with advantage, but even if the authorities had taken the same view, any attempt to substitute female nurses for the orderlies to such an extent as is the case in a civil hospital would have dislocated arrangements most seriously, and would have meant practically the reorganization of the base hospital system in the middle of the campaign, when the officials were already very much overworked. This is, however, I think, a point which should be kept in view when the numerous lessons taught by the war are taken into consideration."

Drs. Sambon and Low's Experiments.—The hut in which Drs. Sambon and Low are making their experiments to see whether malaria is prevented by excluding mosquitos is placed on a site about two miles from Ostia, on the edge of a swamp formerly part of the royal hunting domain of Castel Fusano, and left undrained to preserve the wild animals. It is one of the most fever-stricken centres of the Roman Campagna, and is infested with innumerable mosquitos of the malarial variety.—*Science.*

The Centenary of the Royal College of Surgeons of England.—It is one hundred years since George III. gave to the surgeons of England the right to incorporate themselves into a Royal College, and on Thursday, July 26th, the centenary of this incorporation was fittingly celebrated. Sir William MacCormac, the president of the college, delivered for the occasion an eloquent address, in which, after welcoming the surgeons from other countries who had been adjudged worthy of receiving the honorary fellowship of the college, he proceeded to give a short but interesting review of the development and progress of surgery in general, and of British surgery in particular. Sir William MacCormac's speech has been published in book form, and appended to it is a brief biographical sketch of each master and president of the college since its incorporation.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 17, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Kansas, Wichita	August 4th to 11th	1	
Louisiana, New Orleans	August 4th to 11th	10	2
Minnesota, Minneapolis	July 14th to August 4th	22	
Winona	July 20th to August 4th	2	
New York, New York	August 4th to 11th	1	1
Ohio, Cleveland	August 4th to 11th	1	
Portsmouth	August 4th to 11th	4	
Utah, Salt Lake City	July 28th to August 11th	11	2
Smallpox—Foreign.			
Belgium, Antwerp	July 21st to 28th	2	
Brazil, Rio de Janeiro	June 22d to 29th	..	7
England, Liverpool	July 21st to 28th	1	
London	July 21st to 28th	11	
Germany, Frankfort on the Main	July 14th to 21st	..	2
Mexico, City of Mexico	June 17th to August 5th	62	51
Vera Cruz	July 28th to August 4th	..	6
Netherlands, Rotterdam	July 21st to 28th	1	
Russia, Moscow	July 14th to 21st	3	
Odessa	July 21st to 28th	1	1
St Petersburg	July 14th to 21st	69	15
Warsaw	July 14th to 21st	..	4
Straits Settlements, Singapore	June 23d to 30th	..	2
Switzerland, Geneva	July 7th to 14th	1	
Yellow Fever.			
Brazil, Rio de Janeiro	June 22d to 29th	..	4

THE RELATIVE BEARING OF THE CONJOINED TENDON AND THE INTERNAL OBLIQUE MUSCLE UPON THE RADICAL CURE OF INGUINAL HERNIA.[1]

BY JOSEPH A. BLAKE, M.D.,

ASSISTANT DEMONSTRATOR OF ANATOMY, COLUMBIA UNIVERSITY; ATTENDING SURGEON TO THE ST. LUKE AND HARLEM HOSPITALS.

My chief reason for presenting this subject is that we are in danger of becoming confused in our descriptions of the operations for the radical cure of inguinal hernia. The danger arises from the misapplication of the term "conjoined tendon." It is not my purpose to enter into a long dissertation upon the anatomy of this region, but only to give enough to elucidate the points in question. It may seem superfluous to review these anatomical details, yet if they were understood by all the present ambiguity would not have arisen.

The conjoined tendon is usually understood to be the insertion of the lower fibres of the internal oblique and transversalis muscles, extending along the ilio-pectineal line laterally for a variable distance from the rectus insertion. A careful dissection of this region, especially if the internal oblique be well developed, reveals that as a rule the lowermost fibres of the internal oblique do not enter into the formation of the conjoined tendon, but, arising from Poupart's ligament, in front of the cord, pass parallel with the ligament to be inserted in front of the rectus (Fig. 1).[1] If the internal oblique be reflected the conjoined tendon is found to be chiefly derived from the deeper aspect of the internal oblique, and slightly from the transversalis where these muscles are inseparably connected at their origin. It consists mainly of a few scattered muscular fasciculi arching over the cord, to be inserted to the ilio-pectineal line (Fig. 2).

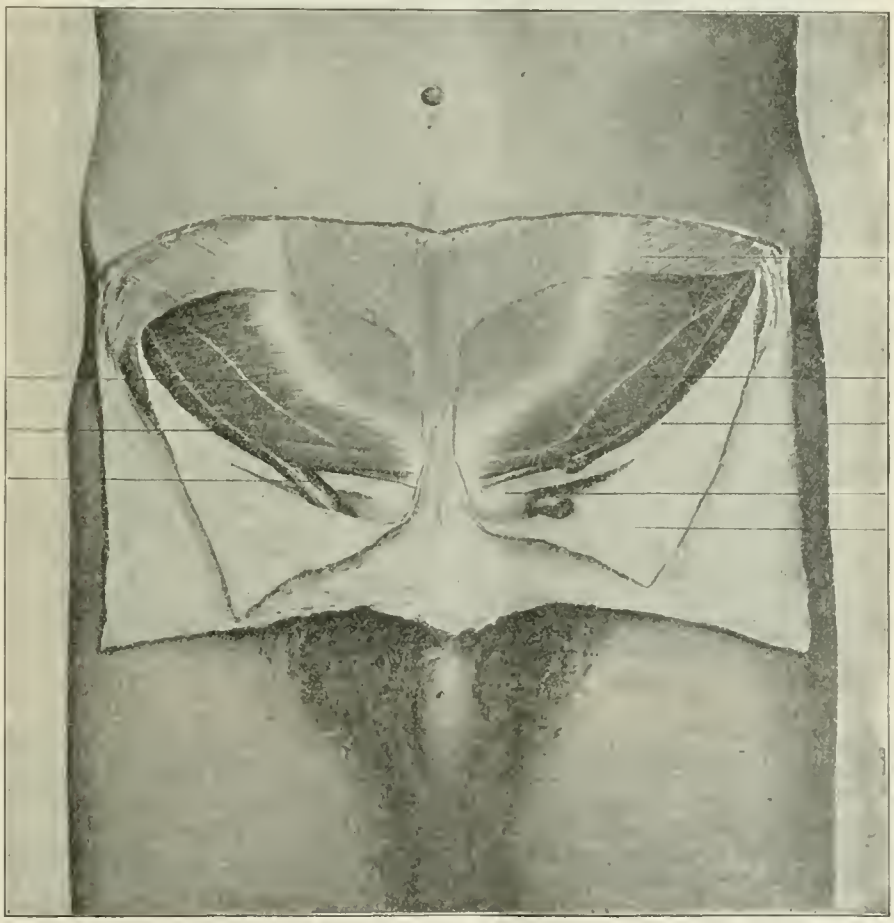

FIG. 1.

The conjoined tendon is thus covered by the lower part of the internal oblique muscle, and also it lies in front of the main aponeurosis of the transversalis, for the fibres of the latter are easily demonstrated as passing behind the conjoined tendon to unite with the internal oblique in front of the rectus (Figs. 2 and 3). This relation is usually overlooked on account of the tenuity of the transversalis aponeurosis in this region.

[1] Read before the Surgical Section of the Academy of Medicine, New York, April 9, 1900.

[1] The illustrations were drawn from consecutive dissections made on the same subject, a man thirty years of age, of moderate muscular development.

In May, 1898, Bloodgood published a preliminary report upon an operation he had devised and practised for the radical cure of hernia. The operation was especially designed for a condition which he calls "obliteration" of the conjoined tendon, and is based upon the suture of the lateral border of the rectus abdominis to Poupart's ligament. Bloodgood explains the use of the term "obliteration" "in that the extreme condition is more likely to be acquired than congenital." He further states that, in cases of obliteration of the conjoined tendon, the whole hand can be introduced into the abdomen after division of the aponeurosis of the external oblique. Obliteration was found by him to occur in seven per cent. of herniæ. He also mentioned the variable development of the conjoined tendon, and refers to the statement in Quain's "Anatomy" that it usually extends over the inner two-thirds of Hesselbach's triangle, but may extend laterally as far as the internal abdominal ring, on reading Quain's description, and after reading Halsted's discussion of Turck's paper on "The Surgical Anatomy of Hernia,"[1] I found it to be the case.

How this error arose can be better appreciated by reviewing the structure of this fascia as well as the literature on the subject. The aponeurosis of the transversalis muscle passes horizontally across the lower part of the abdomen, and in this region is inserted with that of the internal oblique in front of the rectus muscle. For a short distance above Poupart's ligament in the region of the inguinal canal it is deficient, and the structure already referred to as the transversalis fascia is the sole protection to this part of the abdominal wall after removal of the external and internal oblique muscles (Figs. 2 and 3). This fascia presents aponeurotic fibres, which near the rectus muscle have in general a vertical direction, while in the region of the internal ring they have a curved direction, passing from above downward and curving

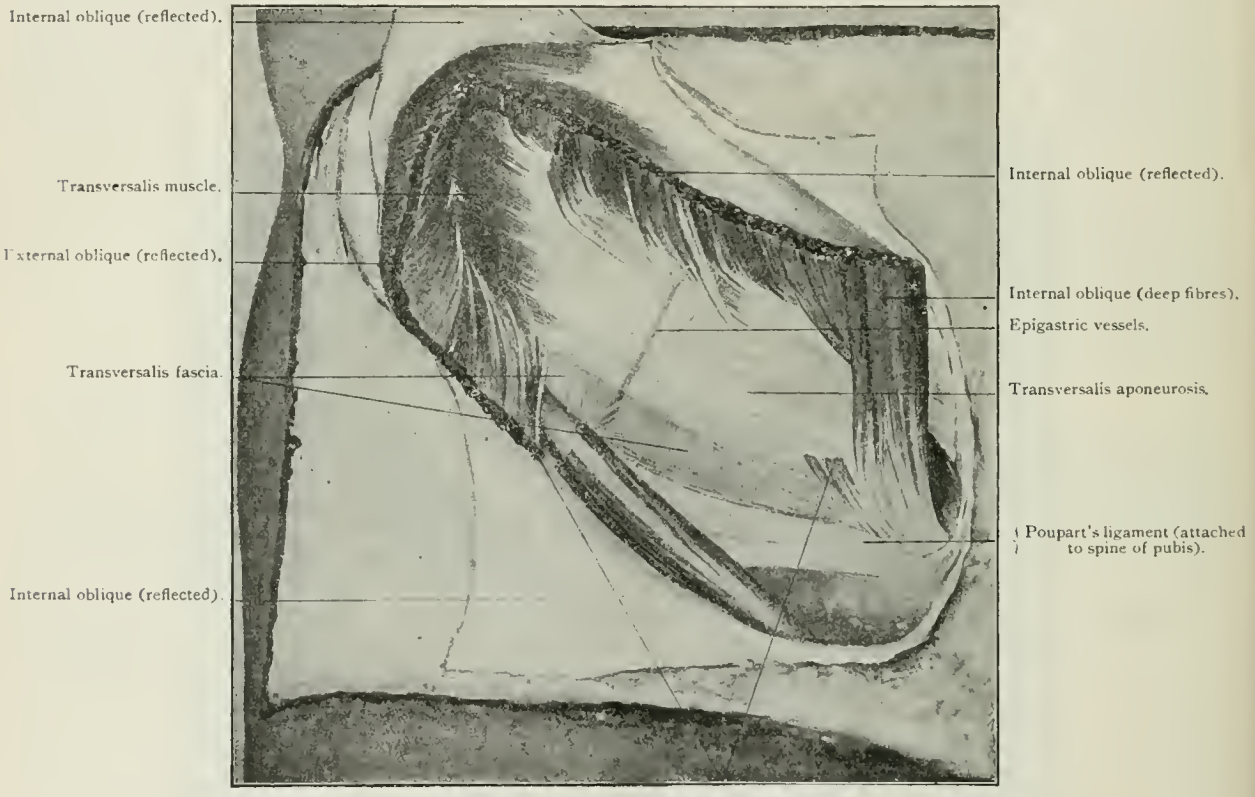

Fig. 2.

which would be a distance of about an inch and a half or two inches.

My impression from casual observation in numerous dissections had been that the conjoined tendon was more or less of a myth, and it seemed to me to be erroneous to attribute so much importance to it. In order to determine this point, I made during the past fall and winter a series of observations in the dissecting-rooms of the College of Physicians and Surgeons, Columbia University. In observations made on both sides in twenty-five selected muscular subjects, in which the parts were normal, I found that in no case did the conjoined tendon extend for more than five-eighths of an inch laterally from the insertion of the rectus. In the majority the extent was less than half an inch, and in some subjects its extent was inappreciable. In all cases it consisted of only scattered muscular or tendinous fibres. There was uniformly, however, a distinct dorsal wall to the inguinal canal formed by the thickened transversalis fascia. It had not occurred to me at first that the Baltimore surgeons referred to this fascia as the conjoined tendon. But sharply around the cord to pass laterally below that structure with a direction in general parallel to Poupart's ligament. These latter fibres form the pillars of the internal ring, and suspend the cord above Poupart's ligament. Between the vertical inner and curved outer portions is a thinner portion through which direct herniæ are said to occur (Fig. 3). This fascia including the aponeurotic fibres lies on the dorsal aspect of the transversalis aponeurosis, being easily separable from it at its lower portion, but above it is closely connected with the transversalis and a separation becomes artificial (Fig. 3). The structure is best viewed from the dorsal surface of the abdominal wall, after the removal of the peritoneum. Often in muscular subjects muscular fasciculi from the transversalis and sometimes the internal oblique may be seen passing into it. It is closely connected above with the extremities of the fold of Douglas.

Henle[2] described the structure as fascia transversalis, and named the portion consisting of the fibres curving

[1] Journal of the American Medical Association, April 15, 1899.
[2] Henle: "Anatomie des Menschen—Muskellehre."

downward to form the inner margin of the internal ring the "ligamentum inguinale mediale," while to the portion below and lateral to the ring he gave the name "ligamentum inguinale laterale" (Fig. 3). The curved margin is also known as the "plica semilunaris fasciæ transversalis."[1] The curved portion internal to the ring is generally known as the ligament of Henle; the outer portion, lying below the inguinal ring or fossa and so above the femoral, is often called the "ligamentum interfoveolare," or ligament of Hesselbach.

Douglass[2] describes the whole fascia as properly an aponeurosis, inasmuch as it is closely combined with the transversalis aponeurosis above and also is connected to both internal oblique and transversalis muscle by muscle fibres. He also states that a fascia that lies between it and the peritoneum is the true transversalis fascia. No doubt the supposition that it is conjoined tendon has arisen on account of his description of the insertion to it of muscle fibres from both

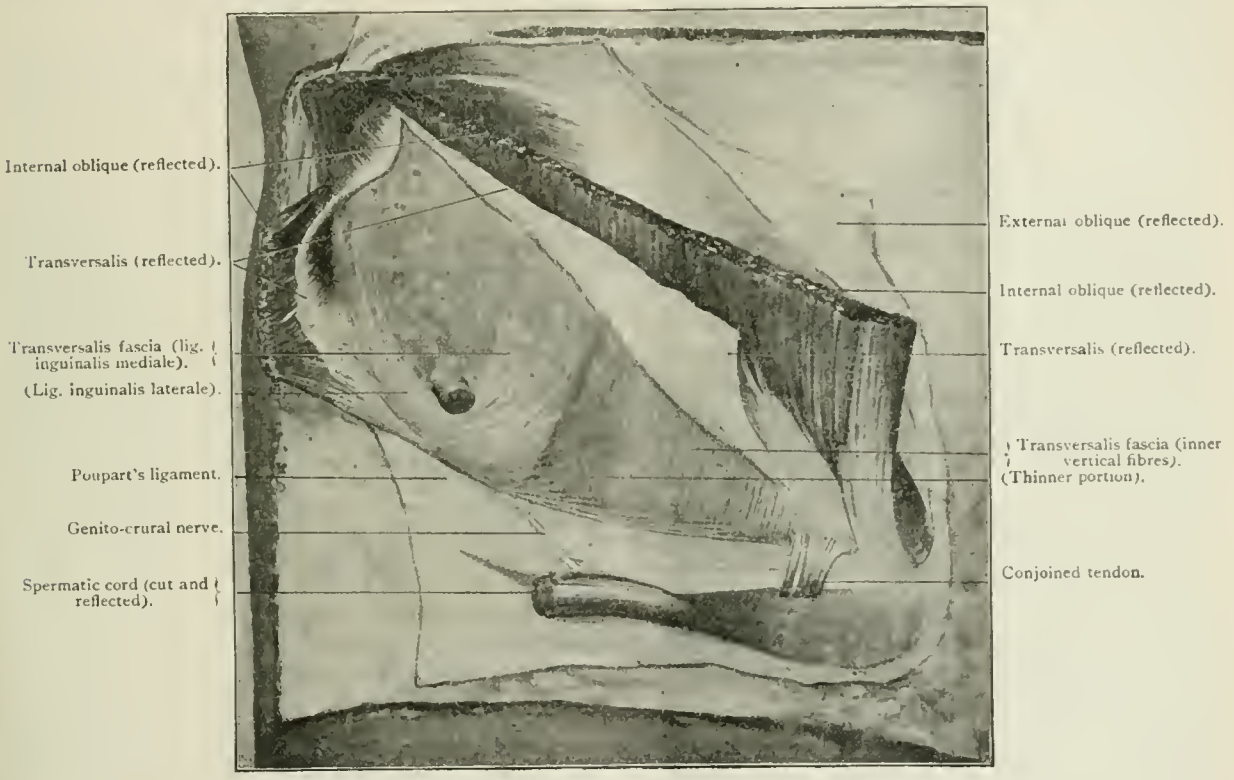

Fig. 3.

transversalis and internal oblique. However, I cannot gather from his article that he calls it conjoined tendon. The description in Quain is based upon Douglass' article, and refers to this fascia or aponeurosis as a part of the conjoined tendon. Bloodgood's position is evidently taken from Quain.

Quain's words are:[3] "The conjoined tendon varies greatly in its development. In many cases it is very slight and scarcely to be distinguished, while in others its deeper portion, derived from the transversalis muscle, covers the whole breadth of the triangle, reaching outward along the deep femoral arch as far as the internal abdominal ring. Sometimes the outer part is detached from the rest, and forms a band which has been designated ligamentum interfoveolare or ligament of Hesselbach, while to the remaining inner portion the name of falx inguinalis or ligament of Henle has been given."

Unless we call this fascia conjoined tendon we cannot accept Bloodgood's term "obliteration of the conjoined tendon." It is entirely distinct from the historic conjoined tendon, being separated from it by the main aponeurosis of the transversalis. Although forming the main support of this region it has nothing to do with the operation for radical cure, except in so far as to determine an operative method, inasmuch as only structures that lie in front of it are sutured. The true conjoined tendon is ordinarily such a weak affair that it is negligible in operative procedures. It is only exceptionally that either it or the transversalis are included in the sutures in the Bassini operation, excepting that the sutures placed in the neighborhood of the internal ring may include the transversalis. Our main reliance in radical cure is the internal oblique, and our efforts should be to restore the normal parallelism of its fibres to Poupart's ligament. This may be done in nearly all cases by separating the internal oblique for a short distance upward from the transversalis fascia and the transversalis aponeurosis, and then, thus having loosened it, it may be drawn down by the sutures to Poupart's ligament. As a rule it is futile to attempt to draw down the transversalis aponeurosis, since this structure is normally deficient for a considerable distance above the ligament (Fig. 2). The normal arrangement of the lower fibres of the internal oblique is well shown in Fig. 1. It shows that they form a considerable part of the anterior wall of the inguinal canal, the lowermost fibres arising, as a rule, from Poupart's ligament for a considerable distance to the inner side of the internal ring. Turck[1] has confirmed this relation in a number of observations.

The method of inserting the suture as employed by Coley[2] restores in a great measure this normal arrangement. Coley employs the Bassini method with the

exception that the first suture is placed outside of the cord. Bassini's and Coley's results are ample proof, it seems to me, that this method is the best we have. Bassini's statistics give less than three per cent. of relapses and Coley's only five relapses in five hundred and forty-nine cases. Methods which are based upon the division of the muscle and the transplantation of the cord between the cut fibres do not give such brilliant results. Although the cord is transplanted to a place where the muscle fibres are more abundant, yet relapses occur chiefly along the cord. According to the statistics at the Johns Hopkins Hospital, over six per cent. of the cases had relapses at this point.[1] It seems to me that there are two reasons for this—first, that the cut ends of the muscle fibres retract away from the cord, and secondly, that the incised transversalis aponeurosis and fascia are not properly repaired. Thus arises a muscular dimple which is a more important etiological factor in the occurrence of hernia than a mere peritoneal dimple. In order to obviate the relapses along the cord, the operators have diminished the size of the cord by either excising the veins, which sometimes causes atrophy of the testicle, or by transplanting only the vas deferens to the intra-muscular position, which it seems to me is simply trying to make the anatomical structure fit the operation instead of vice versa.

In regard to the suturing of the border of the rectus muscle to Poupart's ligament, the procedure cannot be said to be a new one, inasmuch as Bassini[2] in his original article recommended it in some cases. It was also advocated by Wöfler in 1892,[3] who incised its sheath, and Slajmer,[4] in 1898, reported one hundred and fifty cases treated by Wöfler's method.

Incision of the sheath of the rectus on its anterior aspect, as practised by Wöfler, severs the insertion of the internal oblique and transversalis and thus weakens the abdominal wall. Bloodgood overcomes this by opening the sheath behind and then transplanting the muscle.

Bloodgood at first employed the transplantation of the rectus only in those cases in which the transversalis fascia (conjoined tendon?) was obliterated. In fourteen such cases operated upon by this method there were no relapses at the lower angle of the wound, while sixty-two per cent. of similar cases treated by the Halsted method without this modification relapsed. When the transversalis fascia is obliterated, scarcely any additional traumatism is caused by Bloodgood's procedure, but it necessitates the sacrifice of this fascia if it be well developed. For this reason it does not seem to be indicated as a routine procedure.

Tumor of the Soft Palate.—Noquet reports the case of a boy three months old who was troubled with attacks of suffocation becoming more frequent and often occurring when he was asleep. Nursing was interfered with, but between the attacks the cry was perfectly normal. Examination showed a pedicled growth attached to the left free border of the palate and reaching to the base of the tongue. Excision was easily done with traction forceps and scissors, and while there was no bleeding, the fibrous character of the pedicle led Noquet to pass a ligature around it as a matter of precaution. All symptoms quickly disappeared. The mass removed was found to be a fibromyxoma.—*Revue Hebdomadaire de Laryngologie*, July 21, 1900.

THE SIGNIFICANCE OF THE BACILLUS COLI COMMUNIS IN DRINKING-WATER.[1]

By J. H. LINSLEY, M.D.,

AND

B. H. STONE, A.B., M.D.,

DIRECTOR AND ASSISTANT BACTERIOLOGIST, LABORATORY OF HYGIENE, VERMONT STATE BOARD OF HEALTH, BURLINGTON, VT.

The bacteriological examination of water has in the last few years undergone something of an evolution. With the first flash of knowledge of micro-organisms as etiological factors in disease, and the wave of scientific enthusiasm which followed, it seemed that in this discovery lay a direct method for the prevention or cure of all disease. This branch of water analysis assumed perhaps an exaggerated importance to the slighting of the older chemical methods. Great significance was attached to the number of micro-organisms, and it was asserted by some that a water which contained over three hundred bacteria to the cubic centimetre was to be condemned. Gradually a reaction has come, and the pendulum has swung back to more nearly its true resting-place, we may assume.

Now much less significance is attached to the number of organisms per cubic centimetre, and the efforts of the bacteriologist are centred on a determination of the kind of germs present.

The presence of certain species is accepted as a proof that the water has been exposed to conditions of the greatest importance in connection with its fitness for drinking-purposes. The object of the present system is to bring into accord the chemical and bacterial examination. With the chemical is compared the biological, which seeks to ascertain the facts required for a just conception of the general bacterial history of the water, and by a careful balancing of the two results it seems possible to form a just judgment of the sanitary value of the water supply, and to learn whether it contains, or is liable in the future to contain, poisonous substances or the contagia of disease.

The important questions to be answered are: (1) Whether the water has been polluted with sewage, and (2) in case there are many bacteria present, whence they are probably derived.

In water which has been freely exposed to the atmosphere, there are often a large number of organisms present, but these are derived from the air, are not as a rule pathogenic, and consequently are of little importance. The numerical determination is of value if it can be carried on systematically, a daily or weekly record of the numbers being kept as a standard. Any sudden and great variation from this standing will then suggest some contamination.

In the search for the pathogenic, the germ most often isolated is the bacillus coli communis. Before gaining any idea of the significance of the presence of this germ we must have a clear view of what we mean by the bacillus coli communis. But here unfortunately we meet with much confusion. As its name indicates, this bacillus is a common inhabitant of the colon, and is present in the fecal discharges of man and many, if not all, of the animals. It is commonly described as answering to a certain number of constant features in regard to motility, size, and growth upon artificial media. It is sluggishly motile or, according to some observers, motionless; 2–3 microns in length; and its most important cultural characteristics are the production of gas in glucose solutions, the power of curdling milk, and of producing indol by its growth in peptone solution. These growth traits serve to distinguish it from the typhoid bacillus, which it resembles in many other points. But unfortunately for our classification we find in water often, and in excre-

[1] Paper read at School of Instruction for Health Officers, Burlington, Vt., May 24, 1900.

tions sometimes, a number of bacilli which apparently lie between these two groups. Our classification of bacteria is at best an artificial one, and there are undoubtedly a number of undiscovered, unnamed species shading into each other and filling in the spaces between known varieties.

In a series of 509 specimens of water examined at our laboratory, varieties of colon bacilli have been found as follows: 56 which give every typical reaction; 3 which ferment lactose and glucose but do not give indol; 1 which ferments lactose and glucose, does not coagulate milk but does give indol; 3 which ferment glucose and lactose, but do not coagulate milk or give indol; 1 which does not ferment lactose or glucose, coagulates milk, but does not give indol; 1 which does not ferment lactose or glucose, and does not coagulate milk. These varieties, it will be seen, approach nearer to the typhoid bacillus in their characteristics, and the question has been seriously discussed whether the colon bacillus may not under certain conditions become altered so as to assume all the properties of the typhoid, and these pseudo-coli or typhoid varieties be transitional forms. Roux and Rodet came to the conclusion that this was the case, and that the bacillus coli communis when grown in sewage, etc., might become extremely pathogenic and give rise to typhoid fever. Laboratory experiments upon this organism have, however, failed to demonstrate this.

But granting that the two varieties, typhoid and colon bacilli, are entirely distinct, the significance of the bacillus coli communis in water is still of the utmost importance: First, as an undeniable evidence of sewage pollution. Here it is ten times more delicate than any chemical tests, for a mere trace of sewage contamination, so small that there is no appreciable increase in the ammonia or chlorine, will infect such a water with a germ which will increase to an extent that any careful bacterial examination will disclose its presence.

In our examination of five hundred and nine specimens, the bacillus coli communis was found in seventy-eight, and only thirty-one of these were condemned by the chemical findings. In a report on this subject in the *British Medical Journal*, Drs. Klein and Houston emphasize the failure of chemistry to detect pollution of water with minimum quantities of sewage. Sterilized distilled water was infected with sewage in varying degrees representing dilutions ranging between 1:100 to 1:20,000. Chemically these waters would have been classed as at least organically safe for drinking-purposes, but in every one the bacillus coli communis was detected. Moreover, the detection of this organism tells something about the contamination. The colon bacillus will not live indefinitely in water which does not contain so high a per cent. of organic matter as would readily be detected chemically. (In experiments carried on at the laboratory this germ has been found to live two months in distilled water, three months in tap water, and four to six months[1] in sewage-polluted water.) Hence it follows that the presence of a colon bacillus indicates that the contamination is of comparatively recent date, and it also shows that it came probably from the surface.

If at Lawrence five feet of sand can remove disease germs, it probably can do the same in Vermont. It is an old idea that if there is a cesspool up here and a well a little lower down, a figure can easily be traced on the blackboard showing how the filth from the cesspool finds its way to the bottom of the well, perhaps twenty or fifty feet away. The chemical evidence of sewage, chlorine, and ammonia may reach the water, but whenever an infected well is found, the source of the trouble should be first looked for at the top. The large number of waters showing the chemical evidence of sewage alone are probably cases of old pollution or pollution from remote ground filtration, and are comparatively harmless.

So much for the presence of colon bacillus as an indicator; and now (second) what danger does it carry in itself?

Much too little significance has been attached to the pathogenicity of this germ. Because it is found normally in some parts of the intestinal tract and is generally harmless when found there, it has been ignored more or less as a dangerous element. The bacillus coli communis may be, and often is, the etiological factor in many diseases, as cystitis, nephritis, pyonephrosis, meningitis, abscess, sepsis, pyæmia, and septicæmia. In fact it is one of the most obstinate pus producers we know, and is usually the infective agent in appendicitis and peritonitis.

It is generally conceded that there are two great classes of dysentery: one due to faulty digestion, and one, epidemic dysentery, caused by infection. Aside from the rare amœbic form, what is the cause of epidemic dysentery? Filthy conditions, infected water are the usual explanations. Epidemic dysentery is, like typhoid fever, a filth disease: this fact has been recognized since the time of Hippocrates, who wrote a lengthy discussion upon the subject. We in northern climes hardly realize what this means until we stop to think that this is one of the four great epidemic diseases of the world in regard to its mortality. And we can in this age hardly doubt that the trouble comes from micro-organisms in the sewage-polluted water; and the germ concerned is undoubtedly the bacillus coli communis. This is too generally admitted to need much argument. Sternberg in his description of the etiology of diarrhœa says: "Probably the bacilli of the colon and proteus group are more frequently than any others responsible for these gastro-intestinal troubles. They are widely distributed and multiply with great rapidity in favorable conditions." Jensen has investigated a fatal infectious disease of calves characterized by diarrhœa, and concludes that it is due to a bacillus which corresponds to the bacillus coli communis in all respects except in its increase in virulence. In the contents of the intestine of calves which have recently succumbed to the malady, the bacillus is found in almost pure culture; also in inflamed mucous membrane, in hyperæmic mesenteric glands, in blood and various organs. Calves fed with a culture of the bacillus invariably died within two or three days, and the bacilli were found in almost pure culture in the contents of the intestines and in great numbers in the blood and organs. Subcutaneous injection of 4 c.c. of bouillon culture caused fatal septicæmia. Drefus finds a decided difference in the pathogenic virulence of colon bacilli from healthy individuals and those suffering from intestinal disorders. Is it not entirely possible also that some of the groups of colon bacilli set up a case of enteritis in some susceptible person who has, let us say, recently moved into the community; and that these germs, increased in virulence by passing through a susceptible individual and again into the sewage-polluted water, infect others, and thus produce some of the cases of pseudo-typhoid enteritis which do not give the Widal reaction with the laboratory standard typhoid culture? It would seem that such might be the case; and if so theoretically, the blood from such a person should give Widal's reaction with the germ if it can be isolated.

And at this point let us digress to explain this serum, or so-called Widal, reaction. The principle of this phenomenon as used in laboratory diagnosis is, we presume, more or less familiar to most of those present, yet as it is the method constantly employed in the identification of bacteria, and will be referred to frequently in this paper, it is essential that it be clearly understood.

[1] Experiments not yet completed

It was noted a few years ago that the fluid serum of an animal immunized against the bacillus pyocyaneus caused the diffuse turbidity of a culture of this germ in a fluid medium to assume a clotted appearance, the lumps or clots gradually settling to the bottom of the tube, leaving the fluid above clear. Microscopically the germs, instead of swimming about actively as they did normally, showed a great tendency to group themselves together in large bunches and to cease their motions. Later it was discovered that the principle held true with the serum of animals immunized with typhoid, plague bacillus, and the bacillus coli communis —in short any pathogenic motile organism. Finally it was proven that not only the body fluids of animals rendered immune, but the same fluids from patients suffering from any infectious disease, possessed the same property, and further that the reaction occurred only between the serum of the patient suffering from or rendered immune to the disease and the germ of that particular disease. The principle is simple enough, viz., that the germ in its growth produces a toxin which is disseminated through the blood and when sufficiently concentrated is fatal to the organism itself. It was the same reason which caused the soldier boys when confined at Chickamauga Park for a long time to sicken and die, poisoned by their own excretions. The same principle is made use of in a practical way in the production of diphtheria antitoxin.

The phenomenon above described is used for two purposes: (1) the diagnosis of disease; (2) the identification of micro-organisms.

To return to these cases of enteritis resembling typhoid but failing to give Widal's reaction with the typhoid bacillus. It was our good fortune to be able to investigate the etiology of several such cases a short time ago. A gentleman came to the laboratory in the hope of finding the source of infection of several cases of enteric fever which had occurred in his household. The cases, which were at that time three in number, were of a mild character, lacking the delirium of typhoid. The family had recently moved from New York City to this place, their summer home on the lake shore. At our suggestion samples of water, milk, butter, and vegetables were furnished and subjected to bacteriological examination. Nothing which could possibly be considered pathogenic was found in any of these specimens with the exception of the milk, but from this was isolated an exceedingly motile bacillus, apparently belonging to the colon family, but differing from the ordinary bacillus coli communis in its extreme motility, its failure to coagulate milk, and its tendency to produce a diffuse growth in Hiss' medium. These variations from the normal bacillus of the colon seem to place it between this and Eberth's bacillus.

The question arose as to whether this might not be the cause of the trouble, and if so how infection reached the milk. With a view to investigate the former suggestion, specimens of blood from the cases were procured and gave Widal's reaction with this germ and also with the laboratory culture of typhoid, though only slightly. Later the temperature charts with an explanation from the attending physician gave evidence along this same line. These showed that when the milk was not used for some time the symptoms were ameliorated, but upon its re-use the temperature again went up, suggesting a re-infection. When the suspected cause was removed no more cases occurred. These facts seemed sufficiently good ground for deeming the milk the source of infection. The next question was, Whence did the infection gain entrance to the milk? Milk was delivered directly from the cow into the sterilized bottles and found sterile upon examination, excluding this source.

Further inquiry showed that the milk pails, cans, etc., were rinsed, after being washed and scalded, in water from an old well which had not been used for some time, and an examination of the water from this well disclosed the identical bacillus which was found in the milk. The well was situated where it could receive the drainage of the barnyard, and had not been used by the family of the farmer for drinking-purposes for some time. No ill effects had been produced upon the people who had been drinking this milk for months, but when a family unaccustomed to the surroundings commenced using it, the trouble began.

Table Showing Comparative Reactions of Bacillus Typhosus, Bacillus Coli Communis, and the Germ Found in the Milk and Well-Water.

Morphology and Growth Reactions.	Bacillus Typhosus.	Pacillus X.	Bacillus Coli Communis.
Morphology in broth	Well-marked rods five or six times as long as broad, with longer individuals and thread forms.	Ditto with bacillus typhosus.	Short rods two or three times as long as broad, often nearly ovoid; longer individuals occur much more rarely than with bacillus typhosus.
Motility	Actively motile	Actively motile.	Sluggishly motile.
Growth in reference to air.	Aerobic and facultative anaerobic.	Aerobic and facultative anaerobic.	Aerobic and facultative anaerobic.
Stain by Gram's method.	Decolorized	Decolorized	Decolorized.
Growth at 37° C. in:			
(1) Smith's glucose solution 24 hours.	Turbidity in closed arm; no gas.	30 per cent. gas.	20 to 30 per cent. gas.
(2) Litmus milk 24 hours.	Reddened, not coagulated.	Ditto with bacillus typhosus.	Reddened and coagulated.
(3) Dunham's peptone solution 48 hours.	Indol rarely produced.	Indol produced.	Indol produced.
(4) Plain bouillon 24 hours.	General turbidity, slight increase in acidity.	Ditto with bacillus typhosus	Ditto with bacillus typhosus.
(5) Agar-agar 24 hours.	Slight whitish film.	More luxuriant than bacillus typhosus.	Luxuriant yellowish-white growth.
(6) Acid potato 24 hours.	Luxuriant but invisible growth, sometimes slightly yellow.	More luxuriant than bacillus typhosus.	Luxuriant yellowish-white.
(7) Loeffler's blood serum.	Yellowish-white, fairly luxuriant.	Ditto with bacillus typhosus	More luxuriant than bacillus typhosus.
Widal's reaction with:			
(1) Blood from these cases.	Slight	Positive	Negative.
(2) Blood from a known typhoid case.	Positive	Slight	Negative.

In this case you will notice the infection came directly from the milk to the individual. And in my mind this is usually the case. The antiseptic property of the stomach secretions is sufficient to dispose of a small invasion of a mildly pathogenic germ, but when this organism gains lodgment in a soil so congenial as milk, it increases with enormous rapidity, and when millions of bacilli are repeatedly poured into the stomach of an individual of lowered vitality the natural resisting-power is overcome and infection occurs.

Another case along this same line has recently come under our observation. A physician in this city brought to the laboratory a specimen of blood from a case of suspected typhoid fever, and also a specimen of milk which the man had been using. The blood gave the Widal reaction, but no typhoid bacilli were found in the milk. It was, however, found infected with the bacilli coli communis. The blood also gave a reaction with this germ. The physician describes the case as characterized by more than the usual tympanites. At about this time the dairy from which the milk came became afflicted with an epidemic characterized by diarrhœa, and a number of cows and calves died of the disease. This was apparently a case of double infection, as the blood reacted to both typhoid and colon cultures.

Some investigations were made along the same lines during the epidemic of typhoid fever in Belfast, with the following conclusions, and though the cases in Belfast were most of them typical typhoid, there was added an element of infection due to the bacillus coli communis. The investigators (Messrs. Smith and

Tennant) discovered that fifty per cent. of these cases which were diagnosed typhoid gave the Widal reaction with the bacillus coli communis, and of these there were a number which reacted in the highest dilution with this germ alone. In these cases it is difficult to believe that this reaction from the first was due simply to the invasion of the typhoid bacillus. The more natural supposition is that the reaction of the bacillus coli communis in such cases is due to some process of infection for which it is itself responsible, and that in those cases in which there is a reaction with both organisms there is a double infection. In fact we must accept this, or be driven to the other horn of the dilemma and concede that the two germs are very closely related.

Furthermore, the occurrence of the bacillus coli communis in the urine in these cases is another argument for this independent infection. The facts that this occurs often when there is no history of catheterization, and that there are a number of cases on record of a pyonephrosis proven to be due to these germs, are evidence that the infection comes by way of the kidneys in the process of elimination.

In investigating the water supply of a certain town in the State, traces of the bacillus coli communis have repeatedly been isolated, but never at any time have typhoid germs been found. In this town during the fall and winter months there have continually been a number of cases of a mild enteritis, some of which have and some of which have not given Widal's reaction with our laboratory culture of typhoid bacilli. Ten of these cases, which never gave a good typhoid reaction, have been examined in reference to evidence of an infection by the colon bacillus. Six of them have been found to give a positive reaction with the bacillus coli communis, using the ordinary dilution and time limits. The urine, in the only one of these cases in which it was examined, was found to be infected with these germs. One of the four cases which failed to respond to the reaction with either organism proved to be pneumonia, another malaria.

Otto Lerch reports in the MEDICAL RECORD what he believes to be a case of enteric fever caused by the colon bacillus. In this case the patient, after an illness somewhat resembling a typical typhoid fever, died suddenly of heart failure.

The search for the typhoid bacillus in water is carried on with much difficulty, and results are very uncertain. This is due to the fact that the germ does not increase to any extent in water, and so the relatively small quantities which are necessarily handled in an examination may easily contain none of them, and to the difficulty encountered in separating this germ, when present, from the more resistant bacillus coli communis. We cannot, therefore, rely on the failure to find the germ in water as a positive proof of its absence, but we can say that the water contains no typhoid if it fails to show colon bacilli. In the laboratory experiments we have not succeeded in keeping the more virulent germ alive in water over four weeks, while the colon bacillus will live a much longer time and is much more easily isolated.

From the consideration of all these facts we are driven to conclude that waters in which the bacilli coli communis are found to exist for any length of time are dangerous to the public health, and that the only safe course is to condemn all such. An example proving this is the recent outbreak of typhoid fever in West Burke. From the first there seemed good reason for suspecting the water as the source of the trouble, and samples were sent to the laboratory and examined. The cases in this town were undoubtedly typhoid, but no typhoid bacilli were found in the water. It was, however, found infected with the bacillus coli communis. If the water had been examined before the outbreak and found contaminated, as it undoubtedly was, the trouble might have been averted.

In reply to the argument which is sure to be advanced, that people have drunk the waters which you condemn, for years, and are still living, we may use Professor Sedgewick's words in answer to a similar argument: "Look here, did you ever see a G. A. R. procession? They look pretty healthy. Well, then, war isn't a bad thing, judging by these people." Now the point is the same in both cases. These are the survivors. We don't see those who are lying in the graveyards hereabout or at Arlington or elsewhere, and because you and I and a half-dozen others have been tough enough to stand all of these things, it does not follow that a lot of people have not died of them or will not if subjected to the same conditions.

In this State, when so large a per cent. of our waters are pure, it is perfectly practical and will be highly profitable, not only hygienically but financially as well, in the long run, to discard all supplies which are permanently infected with the bacillus coli communis.

PATHOLOGICAL PHYSIOLOGY OR EXPERIMENTAL PATHOLOGY, ITS SCOPE AND SIGNIFICANCE IN MEDICINE.

By ISAAC LEVIN, M.D.,

NEW YORK.

THE ancient notion, that a disease is a certain independent entity added to the organism, and that it is only the disease, and not the organism itself, which the physician has to deal with, has as yet a strong hold on the profession. The study of pathological physiology, which deals with the abnormal functions of different organs, alone can show that nothing is added to the organism in disease, but that it is only its functions that are changed. The science of pathological physiology has been in existence nearly a century, and its importance in medicine is fully recognized. Still there are very few medical schools in existence in which the subject is systematically taught. I therefore think that it may be of some interest to give a short review of the present state of this science. I hope that my readers, after the perusal of the following pages, may see clearly that medicine is not only an art, but a science in the full meaning of the word, that the logical reasoning on a scientific basis of observation and experiment is of more importance than all the patented and other nostrums, and also that pathological physiology is the real philosophy of medicine. By this I do not mean to say that it is a science which attempts to explain every phenomenon of a disease by mere force of abstract argument, but I do say that pathological physiology is a science which analyzes the observations of the clinic and pathological anatomy and chemistry, and verifies by experiment the conclusions derived from these observations.

The relation between this science and the other branches of pathology will be best understood after the explanation is given of the meaning of the words "diseased or abnormal state of the organism."

An organism is normal and healthy when it receives the greatest possible benefit from the work or functions of every one of its parts or organs. It is only by the aid of the work of these organs that the organism itself, as a unit in the external world, is enabled to perform those life functions which distinguish it from unorganized objects. If the work of its organs ceases, the organism becomes an inert, unorganized body—it dies. But it may also happen that though one or more organs are unable to give the required amount of assistance to the organism, the latter will

be able to compensate the deficiency in one way or another, and continue to live. Such a state of the organism is, however, certainly abnormal, diseased, and, as already stated, the organism will suffer not only through the deficiency of the organs primarily diseased, but also through its consecutive deleterious influence upon the other organs. It should here be added that the function of a certain organ may be abnormal, and still be able to give to the rest of the organism the necessary assistance. Such a state, though abnormal, will not be pathological. A diseased state of an organism is consequently an abnormal state, in which the functions of one or more organs are so changed that they are not only unable to give the organism the full benefit of the work allotted to them, but may even produce a deleterious effect upon the rest of the organism.

It follows that in studying a diseased organism we shall find some or all of these functions changed; in other words, no matter how well normal physiology may explain the functions of the same organism in its healthy state, we shall still have to study the diseased organism anew, *i.e.*, we shall have to develop a morbid or pathological physiology. It is obvious that in disease the structure and chemical nature of an affected organ are also changed, and notwithstanding the perfect knowledge we have of the organism in its normal state, we must make a new and just as complete study of it in every direction in its diseased state.

Pathology in the broadest sense of the word may consequently be considered, in the same way as biology, a group of sciences, studying the structure of a diseased organism (pathological anatomy), its chemical composition (pathological chemistry), and its functions (pathological physiology).

That pathological physiology must be considered a science independent of either pathological anatomy or chemistry hardly needs elucidation. A change of structure of the same character may produce entirely different functional disorders in two different organs, and consequently have an entirely different influence on the entire organism. On the other hand, the same functional disorder may be accompanied in one case by a quite characteristic change of the structure of a certain organ, while in another case we shall hardly be able to discover any change at all.

A great deal nearer are the relations between the pathological and normal physiology. They both deal with functions of the different organs. Pathological physiology avails itself of almost the whole technique of normal physiology. Still the nature of the questions with which these two sciences are concerned are entirely different; many methods which are indispensable in pathological physiology would be superfluous for the purposes of normal physiology.

In the following lines I shall attempt briefly to outline the scope of pathological physiology, and to show that the subject-matter of that science, the questions it has to solve, and its methods of research are different from those of the other medical sciences, and that pathological physiology has a fundamental importance for medicine as well as for biology.

Morphologically an organism consists of a conglomeration of different cells. If we, therefore, undertake to study the pathological changes in the structure of an organism, *i.e.*, the pathological anatomy, we have to consider the cell as the independent unit for investigation. But we must apply a different method when it is our object to study the abnormalities of the functions of an organism. While each of the cells of the body of the very lowest animal can perform the same work as any other of its cells, the cells in the animals of a higher development are greatly differentiated. Not only is every cell restricted to a certain kind of work, but if severed from the rest of the cells of the same group, from the organ of which it is a part, it ultimately dies; consequently a certain kind of work, a certain function can be performed only by a union of like cells, by an organ, and this organ only is the unit for examination in pathological physiology.

An individual thus needs a certain amount of material—food and oxygen, which it receives from the outside, through its lungs and alimentary organs. The food after having undergone certain preliminary changes in those organs is distributed by the aid of the circulatory system all over the body, penetrating into the cells in which it undergoes its final transformation. The cells again discharge into the circulatory channel whatever is eliminated from their body during the process of assimilation of the food, or some other work they have to perform. The substances so eliminated, either having undergone some subsequent changes in the blood or unchanged, leave the organism through the excretory organs (lungs, which consequently do double work, skin, and kidneys). Thus assimilated food is the source of a certain amount of energy existing in the organism, which expresses itself in animal heat, and in the work of the muscular, nervous, and genital systems.

From this enumeration of the functions of the different organs it is easily seen that there is the closest relation and dependence between them, and that an abnormality of one of them must affect all others. Consequently, unlike the study of pathological anatomy, in which even a separate study of a certain part of the body may give us some results, we have to study in pathological physiology not only the abnormality of the function of a certain organ, but also the influence such an abnormality has upon the rest of the organism.

The abnormality of functions may be of two kinds: quantitative, *i.e.*, the function may retain its character, but may increase or decrease in degree; or qualitative, when the character of the function itself is changed.

In the next pages will be given a brief sketch of the scope of pathological physiology. I shall start with the circulatory system, as the influence of this upon the life of the whole organism is most manifest.

Pathology of the Circulation.—The circulatory system practically consists of two parts, the circulatory system proper on one hand and the blood and lymph on the other. The function of the circulatory system consists in propelling the blood from the different parts of the body to the lungs, where it comes into close contact with the inhaled air and gets the necessary amount of oxygen, and from there again to the different organs. The heart is the most important propelling power. Its increased work can hardly be considered a pathological condition, because, no matter how much the quantity of blood coming to a certain organ is increased, the cells do not take from the blood nor return to it any more substances than they would under normal conditions. But a decreased work of the heart, its weakening, is injurious to the organism not only because the supply of blood to the different organs is decreased, but also because an abnormal quantity of blood is gathered in the venous system, which in its turn produces secondary changes in the organs.

But the action of the heart may also undergo qualitative changes, and these are of the gravest consequence to the organism as a whole. The qualitative changes are caused by some morphological lesions in the openings leading from the auricles to the ventricles, or from the latter to the arteries. Those openings are provided with valves, the function of which is to prevent the blood from returning. All those openings may become narrowed, stenotic, or the valves may be unable to close perfectly. Let us consider the case in which one of the auriculo-ventricular apertures

has become stenotic. Only part of the blood normally drawn into the ventricle during the diastole will find its way in; another part will be left in the auricle and consequently in the venous system. Should, on the other hand, the bicuspid or tricuspid valves be insufficiently closed, then part of the blood during the systole will return to the auricle and consequently again overfill the venous system. In a word, whichever of these openings becomes abnormal, the result will be of the same character, *i.e.*, part of the heart's energy will be wasted. The heart hypertrophies and is thus enabled for a certain time by increased energy to do the amount of work necessary for the organism, but like every muscle the heart becomes tired out by overwork —it does not propel a sufficient quantity of blood into the arterial system, and the blood consequently stagnates in the veins. The whole organism suffers, on one hand, from the mechanical and chemical influence of the accumulated venous blood, and on the other hand from an insufficiency in the supply of fresh arterial blood; the different cells of the organs degenerate, the parenchymatous organs become congested by the increased quantity of the venous blood, which also produces a hydrops. It may be here added that formerly when we made an autopsy and found great morphological changes of a certain nature and at the same time a certain lesion in one of the apertures of the heart, it was a very tempting hypothesis that the latter was the cause and all the rest only the sequence, but it was no more than a hypothesis until experiments performed on animals produced on the latter the same lesions in the apertures of the heart, and, as a result, the same functional disorders and the same morphological changes at the autopsy which we met with in a human body.

The arteries are normally assisting the heart's work, and if their walls are changed by some disease process and lose their elasticity, the heart has to perform an increased amount of work, it becomes overworked; this in its turn influences the organism in the manner previously described.

The amount of blood contained in an organism is not sufficient to furnish every organ with the quantity necessary during its activity; as a consequence an active organ receives a larger quantity of blood than an inactive organ. Cl. Bernard has shown experimentally that this constant change between a local physiological hyperæmia and anæmia is due to the influence of the nervous system. If the quantity of blood contained at a certain time in some part of the organism is increased or decreased without regard to the requirements of the normal function of that part, such a hyperæmia or anæmia becomes pathological. A local hyperæmia is called "active" when the quantity of blood is increased through a greater influx of arterial blood. Such a hyperæmia, as already mentioned before, has hardly any deleterious influence upon the functions of the organism. It is true that inflammation, which is also accompanied by an arterial hyperæmia, does change the function of the organ which it affects, but there are other reasons for this. In the first place, in inflammation the stream of blood is not accelerated as in an ordinary arterial hyperæmia, but on the contrary it is even slackened. On the other hand, the causes producing the inflammation show their influence not only upon the circulatory system, but also greatly on the cells of the affected organ itself and thereby only they injure its function.

A stronger influence upon an organ is exerted by a passive or venous hyperæmia, *i.e.*, a condition in which the influx of arterial blood is normal, but for some reason or other the organ cannot be freed from its venous blood. This blood accumulating in increasing quantity injures the organ, first by the mechanical pressure it produces on it, and then by the poisonous action of the venous blood on the cells of the organ (this will be better understood later).

The influence of a local anæmia on an organ is obvious: it produces inanition. The more delicate an organ is in its function (the brain, for instance) the less it is able to sustain anæmia without injury. Not only may the quantity of blood in an artery be decreased but the artery may become entirely impermeable at some point. At first thought we should expect that the part of an organ fed by this artery would die, but it usually does not. The interchange of material between the cells of an organ and the blood begins in the capillaries. Before an artery merges into its terminal capillaries, however, it usually anastomoses at frequent intervals with the arteries of the neighboring regions, and such an anastomosing artery will always exist between the obstructed part of the artery and its capillaries. This anastomosing artery will also supply blood to the capillaries of the obstructed artery. But in some organs (spleen, kidneys, brain, lungs, retina) the arteries do not have an anastomosis on their entire length (such arteries Cohnheim called "terminal arteries"). Consequently if the artery becomes obstructed below such an anastomosis, the corresponding part of the organ becomes necrotic and its function ceases. The fact that an obstruction of an artery by a thrombus or embolus produces a local necrosis in one case and does not in another was known long ago, but its explanation could be found only after the wonderful experiments of Cohnheim, who compressed a minute artery of a frog's tongue (a terminal artery) and studied the results under the microscope.

Blood is the most wonderful organ with the most complicated and manifold functions, some of which we are only commencing to discover now. Like any other organ, blood consists of cells endowed with certain functions and an intercellular tissue, but while in every other organ the latter serves only as a support for the cells, the blood serum has a great many functions to perform, and this not only as transporting cells as well as diluted substances from one place to another, but probably also as an agent producing some chemical changes in these substances.

Of the blood cells we are most familiar with the function of the red corpuscles. Each cell contains a certain amount of a substance called hæmoglobin, which coming into contact with the air in the lungs combines loosely with its oxygen, then turns to the tissues of the body and just as freely distributes it among the cells of the latter. Now, should the number of all the red corpuscles in the body, or the quantity of hæmoglobin in each cell, decrease, the condition of the whole organism will in either case become pathological, as every cell, every organ of the body will suffer from lack of oxygen. Such state of the organism is called anæmia. An increased number of red corpuscles or quantity of hæmoglobin is hardly ever to be met with and is not injurious to the organism, as no cell in the organism consumes more oxygen than it really needs.

We know much less of the functions of the other cellular part of the blood, the so-called leucocytes. This is a chapter in pathological physiology in which we have no normal physiology for a basis, the reason probably being that the most easily observed function of these cells begins only after the organism has become diseased.

Metchnikoff was the first to show that if we introduce into an organism some microbes, we will soon find them inside of the leucocytes (in a degenerated state), and he thereupon developed the theory of phagocytosis.

The leucocytes are consequently for him analogous to an army, which mechanically destroys any parasite

that would otherwise injure the organism. Further research showed that this function of the leucocytes is not a mechanical one only; it seems that, bacterial or any other poison being present in the blood serum, the leucocytes produce certain substances, eliminate them also into the blood serum, and thereby protect the organism against injuries from the poison. It was further shown clinically as well as experimentally, that as soon as a certain poison is introduced into the organism the number of the leucocytes is greatly increased. This increase occurs in so short a time after the influence of a poison on the organism commences, that it can certainly not depend upon a new formation of leucocytes. Facts seem to prove that the increase is due to the so-called chemotactic influence of the poisons, *i.e.*, to the fact that the poison circulating in the blood attracts a number of leucocytes contained as a kind of a reserve force inside of the blood-forming organs (spleen, lymphatic glands, and marrow of the bones). Having entered the blood, these supernumerary leucocytes begin to participate in the work of protecting the organism. Further experimental research in this line throws light on some of the most puzzling questions of pathology. But while the results accomplished are of the greatest importance and benefit to mankind, the field of work opened by these researches is quite unexplored as yet, and will surely lead to innumerable discoveries of the greatest importance.

It has long been known that some species of animals are refractory, immune against certain diseases of other species; further, an organism, after having passed through a certain disease, may remain immune against the same disease for some time or even its whole life. It has also been shown by the wonderful experiments of Pasteur and others that by subjecting an animal to the influence of the attenuated virus of a certain disease, we can make the animal artificially immune against it. The most probable explanation of natural as well as acquired immunity is the following: All cells of the body, and chiefly the lymphocytes and leucocytes as was lately shown, produce, most probably by their nuclei, some substances, alexins, which arrest the growth and kill the invading bacteria. These bacteria are consequently not pathogenic for the organism. On the other hand, if pathogenic bacteria penetrate into the organism, they produce some substances which neutralize the alexins, and the bacteria are enabled to thrive and produce toxins, which serve as a general poison to the organism. If the organism has recovered from the effect of an invasion of pathogenic bacteria, that will show that the organism has produced more alexins than it usually does, and killed the bacteria, or else produced antitoxin and with it neutralized the bacterial toxins, while leaving the bacteria themselves alive. In many instances an organism, after having once recovered from a certain bacterial invasion, is able for some time or even for the whole life to produce such an amount of alexins as to be immune against the same bacterial invasion. Such an immunity is called an acquired active immunity. An artificially acquired active immunity will then simply mean that the organism was trained to produce more alexins, not by having passed through a certain disease, but by an introduction of an attenuated poison of certain bacteria.

If the blood serum of an immunized animal contains an increased amount of alexins it may, if introduced into another animal suffering from the same disease, cure it. This supposition has proved to be true for diphtheria and tetanus, and in time may give us many more therapeutic acquisitions. Such an immunity, when the organism is not trained to produce more alexins but is simply given an extra amount of them, is called passive acquired immunity.

All this protective work is probably not the only function of the leucocytes; at least it does not explain why an increase in the number of the leucocytes, which ought to be beneficial to the organism, is the most conspicuous feature of a grave disease (leukæmia) always leading to death, though here also the leucocytosis may be only a secondary reaction to some poisoning of the organism unknown to us. Neither the normal nor the pathological physiology of the leucocytes can therefore be considered a solved problem.

Blood serum has for its function the transmission to and from every cell of the body of different substances of its metabolism, consequently the abnormalities of its function depend upon and are best studied with the abnormalities of the general metabolism. It need only be stated here, that the function of the blood serum may decrease or cease entirely in a certain part of the body, simply through the change of its density. Blood may coagulate inside of the blood-vessels, obstruct them, and thereby produce a local anæmia.

Pathology of Respiration.—Under respiration we understand a series of functions as a result of which cells of an organism are constantly being supplied with an amount of oxygen necessary for their metabolism and eliminate the produced carbonic oxide. The functions accomplishing this work are the following: The lungs receive from the outside atmosphere the oxygen; the red corpuscles of the blood come in near contact with this oxygen, combine with it, and then carry it to the different cells of the body. These cells receive from the red corpuscles the oxygen and transfer to them their carbonic oxide. The carbonic oxide is being received by the red corpuscles and carried to the lungs, where it is being eliminated. I have already analyzed the functions of the red corpuscles; of the use which the cells of the organism make of the oxygen I will treat under the head of general metabolism. What concerns us now is the work of the lungs themselves, or the so-called external respiration as distinguished from the other respiratory functions which are called internal respiration.

The function of the respiratory organ may be changed in one of the following three ways: Either the air tubes leading to the alveoli may be obstructed (foreign bodies, tumors, bronchitis, and so on), and then, though the respiratory movements are the same, the alveoli do not receive the amount of air necessary for their ventilation; the blood consequently receives less oxygen and is also unable to free itself of the carbonic oxide. Or the alveoli may be filled with some other substance than air (exudate in pneumonia, fluid in œdema, etc.); then the blood does not come in natural relationship to the air and consequently is unable to take in oxygen and eliminate its carbonic oxide. Or, lastly, the air tubes may be free, but the musculo-nervous apparatus (the respiratory muscles, vagus, phrenicus, the respiratory centre in the medulla) and the respiratory movements are changed. Should the obstruction be complete, all the alveoli filled, or the musculo-nervous apparatus cease to work—then the whole organism will be deprived of its necessary supply of oxygen and on the other hand be overfilled with carbonic oxide, which is poisonous, and the organism must consequently die.

On the other hand, should the changes be partial, then if it is the musculo-nervous apparatus which is affected, the function of the respiratory organ will change accordingly. But the result becomes more complicated if the air passages are partly obstructed or some of the alveoli are filled with a foreign substance. In both instances the arterial blood flowing from the lungs will contain less oxygen and more carbonic oxide than normally. This will affect the whole organism, but first of all the respiratory centre, which will become irritated and will increase its work

and as a consequence the respiratory movements. The inspiration becomes deeper and more frequent, the expiration becomes active—*i.e.*, not only is the air forced out by the elasticity of the lungs but also by active muscular work (of the abdominal and some chest muscles). Such an increased respiration is called "dyspnœa." It is easily seen, then, that dyspnœa is a kind of a compensatory action of the organism against a decrease of work by the respiratory apparatus. As a matter of fact it has been proven experimentally that the amount of oxygen used and carbonic oxide eliminated during dyspnœa is nearly the same as that during normal respiration of the same organism. The inference may be made, that an abnormality in the function of the respiratory organ is never injurious to the organism, is never pathological. We know, however, that dyspnœa injures the other organs and is certainly a pathological condition. The reason must be looked for in the fact that dyspnœa increases the gas metabolism by the aid of increased muscular work, and such an increase of work necessitates again an increase in the amount of oxygen used and carbonic oxide eliminated. Dyspnœa, then, though it brings the amount of oxygen and carbonic oxide to a normal level, is unable to increase the amount sufficiently for an animal in such a state. The arterial blood leaves the lungs with a normal amount of oxygen and carbonic oxide, but it goes to organs that do more than a normal amount of work; consequently they take from the blood more oxygen and give it more carbonic oxide than normally. This venous blood, abnormally rich in carbonic oxide and poor in oxygen, cannot, therefore, receive in the lungs the necessary amount of oxygen and eliminate the necessary amount of carbonic oxide to become normal arterial blood, though the work of the lungs is normal. That this is so is proven by the fact that dyspnœa producess cyanosis, a state in which even the arterial blood contains abnormally little oxygen and an excessive amount of carbonic oxide. But in order to prove the above supposition we should have to show experimentally that there really is a difference in the amounts of oxygen and carbonic oxide in the blood of a normal animal and of one in a state of dyspnœa. Such experiments have not been made yet, though the amount of oxygen and carbonic oxide in the blood of a normal animal has been determined.

Pathology of Digestion.—The food which a higher organism gets from outside must contain albumen, fat, carbohydrates, salts, and water. All these substances except salt and water have to undergo certain preliminary changes, chemical as well as physical, before they are fit to be used as food by the cells of the body. This preliminary work is allotted to the digestive apparatus. Beginning with the mouth and ending with the anus, this apparatus consists of a series of organs, each doing its part in the digestive function.

Almost every kind of a pathological state in any of these organs produces the same influence on the organism. On the one hand, it is not all the food taken in that undergoes the necessary preliminary transformation, and the organism suffers from partial inanition. On the other hand, parts of the food transformed and untransformed stagnate in the digestive tract. The micro-organisms that are always swallowed with the food have a better opportunity to act on it and split its chemical substances into different ones, which may prove injurious (poisonous) to the organism.

Pathology of Metabolism.—The assimilation of food or metabolism, as we have seen, consists of three acts—introduction of food, assimilation proper, and the elimination of the remnants of the food. The same three divisions we must follow in studying the abnormalities of the metabolism.

The food may be introduced into the organism in an abnormally increased quantity. The influence of such an increase is hardly of any importance. The quantity of food taken in by the cells of the organism does not depend on the amount of the supply of food on hand, but upon the amount of substance necessary for the cell to cover its expenditure, consequently upon the amount of work produced by the cell. The only injury an organism can receive from overfeeding is the overloading and stagnation of food in the digestive tract, or overexerting of the excretory organs.

A great deal more important is a decrease in the amount of introduced food or a total absence of food. Certain functions have to go on in an organism so that its life may be continued. These functions will then go on even though the supply of food has ceased. At first the cells find in the body a sufficient amount of stored-up material (fat, carbohydrates), by which they can recuperate their loss. But when this is all used up, the cells, while continuing their functions, lose so much of their own substance that they are unable to continue them, and die. In this instance there manifests itself the most wonderful capacity of the whole organism for self-preservation. For those cells which are of the greatest necessity to the whole organism (nerve cells) live longer than the rest, and most probably feed themselves on the substance of less important cells (fat).

Now, the substances introduced into the organism can also differ qualitatively from the ordinary food. *A priori* we have to suppose that such a substance introduced into an organism (I mean by it not only brought in the digestive tract, but also absorbed by the blood) will be eliminated again without being taken in by the cells; and this is really the case with some substances. But there is a large class of substances which, when introduced into the organism, are taken in by the cells, and, though unable to serve as food in rebuilding the cell, these substances influence the latter so that its function is either improved, impaired, or even stopped entirely. To the first class belong the medicative agents, to the latter the so-called poisons.

The study of poisons has now acquired such a predominant place in the whole field of pathology that it would be impossible for me to give here even the merest outline of the matter. We understand a poison to be a substance which, when introduced into the circulation, produces upon some cells of the organism such an influence that the function of these cells is either interfered with or stopped entirely. What the nature of the action of a poison is we are absolutely unable to say. Still there are a great many questions in physiology, normal as well as pathological, which could be answered only through the study of the action of poisons, and a great many more that will probably be answered through such a study in the future. The fact that a great many mineral substances as well as substances produced by or derived from plants or animals are poisonous, if introduced into another organism, was known in medicine from time immemorial. But poison was considered a factor rather subordinate in pathology, while at present we have facts enough to prove that poisoning plays a dominant rôle in the whole field of pathology. The etiology of the most numerous class of diseases, the so-called infectious ones, was absolutely unknown until, beginning with the works of Pasteur and Koch, it was shown conclusively of some of them and made very probable for the rest, that they are produced by the influence on the organism of certain well-defined micro-organisms. It has been further proven, as just stated, that this influence does not consist in a mechanical action of these microbes, as was at first believed, but that the micro-organisms through their own metabolism pro-

duce certain substances, which when absorbed by the blood act as poisons on some cells of the organism.

Even normal food, in case it stagnates in the digestive tract, may become a source of poisoning. Under the influence of some micro-organisms which may exist there, and which by themselves may not be injurious to the organism, the food produces abnormal chemical substances which also act like poisons when absorbed by the blood. The most wonderful biological facts discovered through the study of poisoning are in the first place the inability of the poison after it has been absorbed by the blood to injure all cells of the organism. It seems that certain poisons can penetrate and injure only certain cells of the organism. The other fact is that the same cells which were susceptible to a certain poison, can under certain circumstances be made to withstand the same poison (I have mentioned it in the section on blood). This fact is true in the case of bacterial toxins as well as of different poisonous alkaloids (morphine, cocaine). Though the nature of the action of a poison on a cell is unknown, we are quite familiar with the manner in which a given poison injures a certain function; but, as already stated, it is impossible to go here into any details of the question.

We turn now to the study of the abnormalities of assimilation of food. This question is very complicated. As was mentioned before, a substance which is assimilated by one cell may have been eliminated by another. We are unable to follow the course of metabolism of each cell separately; the only method left to us is, therefore, to follow as best we can each component of food from the time it has been absorbed by the blood or lymph until it is eliminated from the organism. We will begin with the proteids of the food. They leave the body in the form of urea, and other substances of less importance. It has been shown that within the cells the final products of decomposition of proteids are most probably certain organic acids (lactic, oxybutyric, etc.) and alkali (NH_3). Normally these two substances form a salt. This salt is transported to the liver, where it undergoes an oxidation into ammonium carbonate [$(NH_4)_2CO_3$] which is then transformed synthetically by the liver into urea. Should this function of the liver become impaired by some pathological process (acute yellow atrophy, phosphorus poisoning, etc.), experimental elimination of the organ, or even without any apparent morphological change, then some of the organic acids will be eliminated without their preliminary transformation into urea. This fact is likely to become of some importance in pathology, as the state of coma taking place in the course of diabetes, carcinoma, and some other pathological processes seems to be due to intoxication by the organic acids circulating in the body.

The abnormality in the metabolism of proteids may go further yet and the proteids may be eliminated before they split into a nitrogenous and a non-nitrogenous part. This takes place in fevers, carcinoma, phosphorus poisoning, acute yellow atrophy of the liver, and some other conditions, when the proteids are eliminated in the form of albumoses. Such an abnormality in the metabolism is certainly a sign of great depression in the functions of the cells, since the albumoses practically contain the same amount of potential energy as the proteids themselves; consequently the cells of the body are in a state of inanition, though the supply of food may be plentiful.

Uric acid, which in birds is the most important product of elimination of proteids, occupies a subordinate place in mammals. It has been shown lately that in the latter uric acid is a product of elimination of only a certain kind of proteids, the so-called nucleins (a constituent part of the nuclei of cells). Some cells in the organism (leucocytes for instance) are constantly dying off and undergoing the process of decomposition. There is consequently always material for the formation of uric acid. In some pathological processes, when leucocytosis takes place, and also in leukæmia, we find mostly an increased amount of eliminated uric acid. This tends to show that the increased number of leukocytes in leukæmia is due not to a decrease in their decomposition, but to an increase in formation, for the number of dead leucocytes must increase so that the amount of eliminated uric acid may increase.

There is a disease which has some, though not well-defined relations to the uric-acid formation, and this is gout. The most important symptoms of the disease are painful, inflammatory swelling near some joint, with necrosis of the tissue and precipitation in it of uric acid. At first it was thought that the uric acid was the real cause of the disease. There is, it was thought, an increased formation of uric acid, which accumulates in the blood and then precipitates in the tissues. But lately with the help of improved methods it has been shown that in gout there is no increase of uric-acid formation in the whole organism, neither is there decreased elimination. The more plausible theory seems to be, therefore, that some unknown cause gives rise in certain parts of the organism to such an abnormal state of the cells that they produce locally more uric acid than the blood can absorb.

We hardly know anything about assimilation of fat under either normal or abnormal conditions. It has been proven experimentally that the fat absorbed with the food can be not only oxidized, but also deposited as fat in the body. On the other hand, an organism which does not receive any fat with the food can still increase the amount of its fat, through the splitting of albumin. Now, why do some individuals have an abnormally, even pathologically increased amount of fat? It is possible that the cells of such an organism are able to oxidize only an abnormally small amount of fat, and that the rest is deposited. We may suppose, on the other hand, that the cells split off an abnormally great amount of fat from the proteids of the food as well as from those of the cells themselves. We have not sufficient experimental proof to accept either of these possibilities.

The greatest amount of work in metabolism has been done on the question of the assimilation of carbohydrates, thanks to diabetes, a disease which has puzzled and interested physicians of all times. It should also be stated that we have received a clearer insight into the normal metabolism of the carbohydrates mostly through the study of its pathology; still a great many of our conceptions of the matter are as yet hypothetical. Under normal conditions, all the carbohydrates, after being formed in the digestive tract into monosaccharids, are absorbed by the portal venous system, and carried to the liver. The cells of the liver seem to transform them into insoluble glycogen, storing the latter within themselves. The cells further transform the glycogen into sugar and distribute it in small quantities only by way of the general circulation to the other parts of the organism according to their needs. The following fact may serve as proof: If we feed an animal with sugar, we find an increased amount of sugar in the blood of the portal vein, while in the blood of the general circulation the sugar is taken up by the cells and after having undergone some preliminary changes, the nature of which we do not yet know, it is oxidized into carbonic oxide and water. Now when an abnormally increased amount of carbohydrates is introduced into the organism, then the liver will receive more sugar than it is able to transform into glycogen. The excess of this alimentary sugar will be absorbed by the general blood

circulation, and we have a glycæmia. Furthermore, as all the sugar from the blood cannot be taken in by the cells, the rest of it will be eliminated by the urine; we shall have then a glycosuria. Such a glycosuria though abnormal is not pathological, as it does not interfere with any function of the organism. A glycosuria becomes pathological only if it is the result of a decrease in or cessation of the glycogen-forming function of the liver, when all the sugar absorbed from the intestinal tract passes into the general circulation. But only a part of this circulating sugar can be oxidized in a given time; the rest will be eliminated, and the organism will suffer from partial inanition. Now is pathological glycosuria or diabetes simply an abnormality of the glycogen-forming function of the liver? The experimental study of the question has shown it to be a great deal more complicated, and is hardly yet able to give a definite answer to the question. It has been shown that the extirpation of the pancreas produces in an animal a severe form of diabetes. This fact shows that the pancreas has also a certain influence upon the assimilation of carbohydrates. Whether this influence consists of the formation of some substance which is introduced into the liver and assists there in the transformation of sugar into glycogen, or of something else, cannot as yet be definitely stated.

There are also facts which show that sugar can be transformed into glycogen and stored not only in the liver but in the other organs of the body, and first among them in the muscles. The assimilation of carbohydrates takes consequently the following course: The organs receive sugar from the liver, transform it into glycogen, and then according to their needs transform the glycogen again into sugar. Now, should the glycogen-forming capacity of any of the organs become abnormally decreased, then sugar will accumulate in this organ and from there penetrate in abnormal quantities into the blood. We shall get a glycæmia and glycosuria. Another striking experimental fact, which complicates the question still more, is the so-called phloridzin diabetes. Phloridzin is a chemical body, which, when introduced into an animal, produces a glycosuria, but without an increase in the amount of sugar in the blood. Such a glycosuria can be explained only by a certain influence of the phloridzin on the cells of the kidneys. It has been further proven that an injury of a certain place in the brain also produces a glycæmia and glycosuria. It seems, then, that pathological glycosuria or diabetes can be the result of different lesions, and it is, therefore, most likely not a disease *sui generis*, but a symptom showing that the assimilation of carbohydrates is abnormal in some organ of the body.

The mineral substances of the food cannot be oxidized nor in any other way assimilated by the organism. Still they are of vital importance, and an animal which receives all the other constituents of the food except the mineral substances dies sooner than an animal in a state of complete inanition. As yet we are unable to explain the mode of action of these substances. They are most likely a vital part not only of the skeleton, but also of all other parts of the body, and as some part of the mineral substances is continually eliminated, the loss must consequently be repaired by the food. We know of certain diseases, such as scurvy, rickets, and osteomalacia, which are in all probability results of certain abnormalities in the assimilation of one or another mineral substance. But the manner in which these states are produced is just as little known to us as is the nature of the normal assimilation of these substances.

While studying the functions of the liver and pancreas, we have met with the fact that, besides producing and eliminating certain secretions through their ducts, they perform also some other work, the so-called internal secretion. The latter is of the greatest importance to the organism, and consists in one of the following two kinds of functions: Either the cells of such glands take up some nutritive substances from the blood and transform them in some way, and then turn them to the blood again, or the cells of these glands produce by themselves certain substances and eliminate them into the blood. From the blood these substances pass into other organs of the body and influence there in one way or another their metabolism.

Now there is a series of these so-called ductless glands in the body, such as the thyroid, the pituitary body, the suprarenal glands, the spleen, the lymphatic glands, and to their number must also be added the marrow of the bones. What is their function? Normal physiology was utterly unable to answer this question. It was thought that all these glands had some connection with the formation of blood, but practically they were hardly considered of any importance in the organism. It was left for pathology to elucidate this, as well as some other most difficult questions of normal physiology. The former was first to show clinically, as well as experimentally, that an organism cannot live without the thyroid and dies after its extirpation under symptoms of poisoning. These symptoms consist either in acute irritation of the nervous system—tetanic convulsions—or in slow depression of nervous and mental functions with certain characteristic changes of the connective tissue (myxœdema). Apparently the thyroid is also an important factor in the general metabolism of the organism, though we are as yet hardly able to determine the mode of its action. The cells of the thyroid may absorb some intermediate product of metabolism poisonous to the organism and transform it into a non-poisonous substance. Or the cells of the thyroid may produce some substance necessary for the general metabolism. We have also facts which tend to show that the same kind of function belongs to the suprarenal glands and the pituitary body. We may say, then, that these so-called ductless glands are very likely some kind of regulators of the general metabolism, and any pathological state of the former injures the whole metabolism.

Far less yet are we able to explain the relation to the metabolism of the spleen, the lymphatic glands, and the marrow of the bones. There are facts which show that an organism may continue its normal life even after the spleen has been extirpated. This fact, however, does not yet preclude the possibility that the spleen may have some very important part in the metabolism. Its function may, for instance, consist in neutralizing or transforming some bacteria or other poisons introduced from outside, and this will explain the fact that the spleen increases so often in size during infectious disease. But this supposition needs a great deal of additional experimental work in order to become even a theory.

Pathology of Excretion.—It has been already stated that as the last stage of the assimilation of food there are formed in the organism carbonic oxide, water, urea, uric acid, some other product of decomposition of proteids, and mineral substances. These last products of the metabolism are eliminated by the organism through its excretory organs. Carbonic oxide and part of the water are eliminated by the lungs, the excretive function of which we have already studied. All the other substances are eliminated by the kidneys and the skin.

The kidneys are the most important excretory organs. Their function consists in absorbing from the blood all the last products of metabolism (except carbonic oxide) in an aqueous solution and subsequently eliminating them. It must be added that the cells of the kidneys are also able to change the structure of

some of the absorbed substances, an instance of which we can see in the formation of hippuric acid. Both kinds of function may certainly become abnormal. The absorbing power of the kidneys may suffer in two ways: on the one hand, from causes emanating, as a rule, outside the kidneys, the latter may be enabled to absorb from the blood substances which they could not absorb abnormally. Among these substances are sugar, which we studied already, and albumin. It has been shown lately that one of the albumins which appear in the urine under pathological conditions, *i.e.*, nucleo-albumin, is due to some lesion of the cells of the kidneys themselves. But in most cases albumin is eliminated from the blood as a result of some abnormality either of the blood circulation or of the filtering properties of the cells of the kidneys, or of both. The elimination of albumin through the kidneys, *i.e.*, albuminuria, has hardly any influence upon the rest of the organism. The quantity of albumin eliminated is certainly too small to cause the organism to suffer from proteid inanition. Far more injurious to the organism is such an abnormal condition of the kidneys as makes it impossible for them to eliminate all the substances of decomposition from the blood.

In the course of different diseases of the kidneys there may develop a state of the organism called uræmia. Uræmia may present different phenomena in different cases, but it is always associated with a state of general irritation or depression of the central nervous system, and always shows features common to general intoxication. The explanation of the nature of uræmia has always interested and puzzled physicians. At first it was thought that in the diseases of the kidneys urea accumulates in the blood and is transformed there into ammonium carbonate, which is poisonous to the organism. Then successively salts of potassium, uric acid, and creatin were considered the poisons that produced uræmia. But it has been proven experimentally that none of these substances, though poisonous to the organism, is able to produce all the symptoms of uræmia. Neither has an overaccumulation of these substances in the blood been found in cases of uræmia. There must consequently be some other substances in the urine, the retention of which within the organism produces uræmia. The chemical search for these substances has so far not proven successful. But we have experimental proof that even normal urine is poisonous to the organism. It has been shown that sterile urine of a normal organism, if injected intravenously into a rabbit, kills it under symptoms very like those of uræmia. The quantity of normal urine necessary to kill a rabbit is always nearly the same. It has been further shown that in order to kill a rabbit with urine taken from a diseased organism we have to take sometimes a greater and sometimes a smaller quantity. The latter fact could be taken as a proof that there is overproduction in the diseased organism of those toxic substances that exist in the normal urine. The former, on the other hand, would show that there is retention in the organism of the same toxic substances which exist in the normal urine. The latter fact would then tend to prove that uræmia is produced by retained toxic substances which are normally filtered into the urine. Still this fact alone cannot explain uræmia. We know of cases in which there is a complete anuria for a few days, and still no uræmia follows. The most important factor, therefore, is probably the impaired power of the kidney cells to transform some toxic products of metabolism into non-toxic ones.

The skin is also able to secrete the greater part of those substances which are eliminated by the kidneys, but in such small quantities that the secretory function of the skin is hardly of any importance to the organism. An extensive injury of the skin may damage or even kill the animal, but such an effect then will not be due to the impaired eliminative function of the skin, but rather to the disturbance of the heat economy caused by such an injury.

From the study of general metabolism we saw that this function of the cells of the organism is the most important and extensive one, as it is common to all the cells of the body. The abnormalities of this function result in partial or complete inanition, or more frequently in some kind of poisoning. This poisoning from causes originating within the organism itself, the so-called auto-intoxication, is gaining a predominant place in pathology, and is probably the most frequent and important ultimate cause of disease.

Pathology of the Heat Economy.—The temperature of an organism depends, on the one hand, upon the temperature of the atmosphere, and on the other on the amount of heat in the organism, and any change in either factor must influence its temperature. An organism can withstand a lower atmospheric temperature only up to a certain point, and then its own temperature falls gradually, and the animal dies under symptoms of general paralysis. A so-called "cold," or an influence of an abrupt decrease of an atmospheric temperature in producing different diseases, was in former years considered quite an important factor, but with the advent of bacteriology its significance has been entirely underrated. Lately the opinion seems to prevail that even in infectious diseases a "cold" may have a certain influence as a contributing cause. It is interesting to note in this connection that experiments have been made which show that an animal previously cooled off more readily yields to bacterial infection.

Very high atmospheric temperature is also proven experimentally, as well as clinically (insolation), to be injurious to an organism. The temperature of an animal rises and it dies under symptoms of general paralysis. The cause of death from overheating is not yet clearly ascertained; the most plausible opinion seems to be that the ultimate cause is some kind of intoxication.

A decrease of the temperature through causes emanating from the organism itself does not seem to be of any importance in pathology. The deaths resulting from an extensive injury of the skin have to be ascribed to this cause.

The most important and frequent abnormality in the heat economy of an organism is the increase of the temperature emanating from internal causes, or the so-called fever. There is still much difference of opinion as to what the term fever means. There is certainly a great deal of difference between an elevation of the temperature after mechanical overwork and that which accompanies septicæmia or some other diseases. Some pathologists, therefore, do not consider every elevation of the temperature a febrile one, but say that in fever the temperature has not only to be raised to, but also levelled on, a certain point. This means the following: If we attempt by the help of some agent to reduce a simple elevation of the temperature of an organism, we shall succeed in reducing it and keeping it at norm, even after the agent has ceased to act, while if we do the same with an individual having fever the temperature will not sink entirely to the norm, and will rise again to the former height as soon as the agent ceases to work. Now, this very ingenious theory still does not seem to introduce any qualitative difference between the two kinds of elevation of the temperature. Let us suppose that in the first case the cause which produces fever gives a certain shock to the regulative mechanism and then ceases its action, while in the other the cause acts continually. It is evident, then, that in the first case

the temperature will be easily reduced to the norm, while in the other it maintains its height, because the regulative mechanism gets the second shock before the antipyretic has had time to act. But as long as there is no qualitative difference between the different elevations of the temperature, it is more convenient to call fever every elevation of the temperature due to causes originating within the organism itself.

Now, to what abnormality in the heat economy is fever due? The normal temperature of an organism depends on the relative amount of heat produced and distributed. It has been shown experimentally that the amount of heat distributed decreases in fever. At the same time the amount of heat produced, which under normal conditions would also decrease under the regulative influence of the nervous apparatus, now even increases. The main factor then must consequently be the abnormal function of the heat-regulating mechanism, which works in fever so as to raise the temperature of the organism above the normal. Quite a large amount of experimental work has been done of late, which tends to show that this abnormality in the function of the heat-regulating mechanism is brought about by some kind of intoxication due to the so-called albumoses (derivates of cell or bacteria proteids). It must be borne in mind, however, that these substances producing fever are not identical with the substances producing the pathological process which is accompanied by the fever. Undoubtedly there are also cases in which fever is produced by a simple reflex action through some peripheral nerves on the heat centres.

From all that has been said we can see that heat economy resembles general metabolism in so far as it is the result of a joint work of many organs of our body, and pathological states of heat economy are in most instances special kinds of intoxication by some substances not yet well defined.

Pathology of the Nervous System.—The study of all the manifold functions of the nervous system must go hand-in-hand with the study of the functions of the other organs of the body. The nervous system may be considered the organ which connects the inner life of the organism with the outside world. One class of nerve cells or so-called neurons receives its impulses from the outside. The functions of these neurons must be studied together with the functions of the organs of sense, and it would lead us too far to undertake such a study here. Neither can we dwell here on the vast domain of functions of that part of the nervous system which is treated by the science of normal and pathological psychology. Neurons of the third kind are those which transmit the impulses received from the other neurons to the different organs of the body, the functions of which we had occasion to study before. We shall have to consider here only the functions of the locomotor apparatus. The locomotion of an organism is brought about by two kinds of organs, the passive ones—bones and joints, the rôle of which is mechanical and need not be dwelt upon here, and the active one—muscles, the various contractions of which bring the bones and joints into motion. The function of a muscle is so fully dependent upon the nervous system, that functionally a muscle fibre may be considered simply a continuation of the axis-cylinder process of a neuron. The joint function of the muscular and nervous system gives rise to two kinds of muscular action. The first is a simple reflex action. In certain pathological states of the nervous system this action may be abnormally increased or decreased, or it may even cease entirely. Much more important to the organism is the second kind of muscular action, the so-called co-ordinate movements. There are regions in the brain in which the axis-cylinder process of one neuron transmits its impulse to the protoplasmic processes not only of one but of a number of secondary neurons. The axis-cylinder processes of the latter pass within the spinal cord and leave it to approach the corresponding muscles. As a result the neurons of the so-called motor regions transmit the impulse not to one but to several muscles, and these muscles are so combined that the organism is enabled to perform certain rational movements. If the nervous impulse ceases because of some abnormality of the nerve cell in the brain or the loss of continuity of the axis-cylinder process in the spinal cord, then the function of the muscles also ceases, they become paretic. Again, whenever neurons of the motor region become over-irritated, then the corresponding muscles will produce contractions unnecessary for the economy of the organism; we will see different kinds of convulsions. Epilepsy is a result of some kind of irritation of all the motor regions of the brain.

Besides the abnormalities in the special functions of the different neurons, there are conditions when the nervous system as a whole is affected, as in anæmia of the brain, its increased pressure or commotion. Such states have always a general influence on the organism; they produce fainting, vomiting, slackening of the pulse and respiration, general convulsions, and so on. What the nature of this general influence of the nervous system on the whole organism is, is a question which cannot yet be positively answered. Possibly these actions impair somehow the supply of food to the nerve cells, or else poison the cells by uneliminated products of their metabolism.

Conclusion.—From the perusal of the foregoing pages we can easily see that the subject-matter of pathological physiology resembles closely that of normal physiology. Both are dealing with the different functions of the organism. Still these sciences are by no means identical. While normal physiology studies only one normal type of the functions, pathological physiology has to study every variation of the same function. This makes the science of pathological physiology more complicated, not only because every function may become abnormal in different ways, but also for the reason that every change in the function of one organ is usually accompanied by functional changes in the rest of the organism.

The study of this science must necessarily be experimental. Deductive reasoning on the basis of facts acquired in the clinic or from the study of pathological anatomy or chemistry alone can hardly wholly enlighten us. Every diseased organism we meet with in the clinic presents abnormalities in a number of its organs, and in most instances we are unable to say what organ it was which primarily became abnormal and how it influenced the others. Pathological anatomy and chemistry may show that a given disease is followed by certain lesions in certain organs, but this makes a certain relation between these two factors only probable. In order to change this probability into certainty, we must prove that a certain morphological lesion produced on a healthy organ of an animal will be accompanied by the same functional abnormality that we saw in the clinic.

Neither is it always necessary to produce a certain morphological lesion on an organ in order to change its function, for there are various factors which, though leaving the organ morphologically unchanged, make its function abnormal. Once the function has become abnormal, we can compare it with functional abnormality which we met in the clinic, and also study the influence of this abnormality on the rest of the organism. But to change at will the conditions of existence of an organism means to experiment. Pathological physiology is a science of functions, of dynamic processes, and experimentation alone can solve its prob-

lems. Pathological physiology and experimental pathology may be then considered synonymous.

In applying the results of pathological physiology to medicine, a further difficulty arises from the fact that we can only very seldom experiment on a human being. The objection is always liable to be urged that no experiment on an animal can be compared with the pathological process in the human being, as their organizations are different. There is certainly some truth in this assertion, as there are, for instance, pathological processes that we are as yet unable to produce in an animal (acute exanthemata, tumors, etc.). Some factors producing a pathological process on a human being do not affect an animal, and vice versa. Still in most instances we have a perfect right to transfer the results of an animal experimentation to the study of human pathology. The cardinal functions of the corresponding organs are the same in all animals with a higher organization; the morphological features of the organs also resemble each other very closely. If we then produce in an animal the same lesion which we met in a human cadaver, and notice the same symptoms which we saw on the patient before his death, we can no doubt compare the results. This is the way, for instance, that all the results in bacteriology have been achieved. Neither must we strive always to experiment on animals which stand nearest the human being by the complicated and high development of their organization, but, on the contrary, more use should be made of lower animals than has hitherto been done. The less complicated an organism, the less complicated its functions and the easier it is to study their nature and causes. From these studies it will then not be difficult to pass over to more complicated phenomena.

As was stated above, the experiment in pathological physiology consists in introducing new factors to act on a certain organ. But as our aim is to compare the abnormal function which we have produced artificially with the one met in some diseased organism, the factors which change the function must also coincide in both instances. In other words, before we are able to study the pathological physiology of a certain disease process, we must know its etiology, and as the latter is frequently unknown we must start our study with it. After an abnormality in the function of a certain organ has been produced, we must also study its changed morphological and chemical composition in order to be able to compare it fully with the corresponding organ of a diseased organism.

We see then that pathological physiology, though resembling the normal, has its own problems and uses its own line of experimentation to solve them. Besides this, it employs certain technical methods used in pathological anatomy and bacteriology for instance, but not used in normal physiology. Like every branch of medicine, pathological physiology is closely, we may say originally, united with the other branches of medicine. It may be considered a connecting link between normal physiology, pathological anatomy, bacteriology, and pathological chemistry on the one hand, and the clinic and hygiene on the other. Fed and strengthened by the development of the former, it becomes indispensable in its turn not only for progress in the treatment of diseases, but not less so for the achievement of the highest aim of medicine, the art of preventing diseases. Prevention of epidemics, immunization, hygiene of food, and innumerable other subjects could not have been properly developed without pathological physiology.

A Christian Science Expert recently fell ill in a boarding-house in this city and tried to unthink the thought that annoyed her. She was so successful that an ambulance was called, and she was carried to the hospital in a raving delirium.

THE DISCOVERY OF "UREINE," THE PRINCIPAL ORGANIC CONSTITUENT OF URINE AND THE TRUE CAUSE OF URÆMIA.[1]

By WILLIAM OVID MOOR, M.D.,

NEW YORK.

About one year ago I began studies regarding certain substances which could be easily oxidized, and which gave as a proof of their easy oxidizability the same characteristic blue reaction with a solution of ferrocyanide of potassium and ferric chloride as we observe when morphine or any of its salts is brought in contact with a solution of these two salts of iron. To my great astonishment I found that the human urine contained a large quantity of some organic substance, which gave this interesting blue reaction in a very intense manner. Numerous and exact investigations forced me to the conclusion that none of the known organic or inorganic components of urine could account for this intense blue reaction, and that therefore some chemical body until the present unknown must be the cause of this strange phenomenon. For the last three months I labored in vain to find and to isolate this mysterious body, and almost gave up the task as a hopeless one, when at last, on the fifth day of July, 1900, I discovered that the human urine contained a liquid organic body, in a quantity superior to urea. I wish to state here at once, that this organic liquid is the most characteristic component part of urine, and that, therefore, I shall henceforward designate it by the name of "ureine." It is not surprising that the existence of a metabolism-product of such great importance should until the present have escaped our knowledge, for every urinary analysis has been made with the firmly rooted idea that urine is a liquid composed of water and of inorganic solid ingredients. For obvious reasons it must be evident that the principal scope of this communication will be a description of the method to be employed for the isolation of ureine; an accurate knowledge of its physical and chemical characteristics and of its clinical significance in relation to the pathological conditions of the body can be only the outcome of careful and assiduous investigations by serious workers all over the world.

In isolating this organic liquid, two principal rules should be kept in view: (1) High temperatures must be avoided. (2) Chemicals should be used as little as possible.

The urine to be examined for its liquid organic component, ureine, should be put in a large, shallow, flat recipient and evaporated at a temperature of not over 50° C. As soon as we observe that there is no more vapor ascending from the recipient, we treat the remainder of the liquid with a strong solution of silver nitrate until no more precipitate is formed. We now cool off the liquid sufficiently to promote the separation of the saline and earthy phosphates, and then filter, washing out the filter once or twice with water, until the liquid comes out perfectly colorless. The filtrate is now put into a small cup, which should be rather deep, and heated to 65° C., in order to evaporate the remaining water. New aqueous vapor will be formed but soon the formation of vapor will cease, though the evaporation may still continue invisibly.

To determine accurately whether or not the rest of the liquid contains a considerable percentage of water, the following delicate test is indispensable:

A large mercury thermometer is placed in the liquid and rapidly withdrawn just at 65° C.; we will probably see a puff of vapor ascending from the mercury bulb, which is an indication that the remainder of the urine still contains an undesirable quantity of water. This procedure is repeated at short intervals, and

[1] Communication presented to the Thirteenth International Medical Congress, Paris, 1900.

finally we shall arrive at a point when there is no more vapor ascending from the mercury bulb. We now measure the quantity of liquid which remained and add to it one-half of its volume of absolute alcohol together with powdered pure oxalic acid, 1 gm. for each 100 c.c. of urine used, and after having allowed the newly formed oxalate of urea—$(CH_4N_2)_2 C_2H_2OO_4$—to settle completely, we carefully add a concentrated alcoholic solution of oxalic acid (which is prepared by dissolving 3 gm. oxalic acid in 10 c.c. of hot absolute alcohol) until no further precipitate is formed. The alcoholic liquid thus obtained is filtered, the filter is washed out once or twice with absolute alcohol, and the whole is now exposed to a temperature of about 55° C. (but not over) for about one hour or an hour and a half, being stirred once in a while with a horn spoon or with a glass rod. To facilitate the separation of sulphates and of the other remaining solid ingredients from the liquid organic constituent of urine—ureine—we now reduce the rest of the liquid to a low temperature and filter the same, freely using cold absolute alcohol to facilitate filtration. There is finally nothing but ureine, together with coloring-matters left in the recipient (besides the alcohol, of course). To separate the coloring-matters from the ureine, the alcoholic solution containing both must be treated carefully with a saturated solution of nitrate of mercury—$Hg(NO_3)_2$—until no further precipitate is formed, and neutralized with carbonate of sodium. (It is advisable then to add a sufficient amount of sodium carbonate, so as to render the liquid slightly alkaline.) Filter again and evaporate carefully, resorting to a temperature of not over 55° C. We have thus obtained ureine, the liquid organic component of urine, that mysterious chemical body which is the cause of the intense blue reaction resulting from urine and a solution of red prussiate of iron and perchloride of iron. Ureine resembles in aspect olive oil, is of a pale yellow color, of a slightly bitter taste, gives to the touch the impression of a fatty substance, and produces on paper spots resembling fat spots, though not so marked as those produced by fat. Its specific gravity is about 1.270; it is, therefore, much heavier than water and about as heavy as glycerin. It is freely miscible in all proportions with water and alcohol, whether these latter are of a neutral, acid, or alkaline reaction; it is barely soluble in ether. Its own reaction is very slightly alkaline, almost neutral. My preliminary investigations have led me to the conclusion that this organic metabolism-product of the human body belongs to the group of alcohols of the aromatic series; at a temperature of about 80° C. it begins to split into several bodies belonging to the class of aromatic oxy-acids, and if heated to about 150° C. it leaves behind pure carbon. This organic liquid has a characteristic odor; in fact, it is this constituent of urine which is the cause of its specific odor. Rubbed into the skin it soon produces a sensation of slight burning; there can be no doubt, therefore, that it is the principal cause of the irritating qualities of urine. One of the most remarkable characteristics of ureine is its ability to take up large quantities of oxygen with great facility. The quantity of 50 c.c. of the average human urine can deoxidize 1 gm. of potassium permanganate, and one sample of urine taken from a woman in the ninth month of pregnancy deoxidized with great rapidity over 4 gm. of permanganate to each 100 c.c. of urine; this urine was voided about five o'clock in the afternoon, was of an intense yellow color, and of a specific gravity of 1.030; it contained about 2⅔ per cent. (by volume) of ureine. It is important to remember that the power of urine to take up oxygen does not depend only on the quantity of ureine present, but to a greater extent on the quality of the ureine, on some intrinsic peculiar force inherent in this wonderful organic liquid; I have seen urine, containing less ureine than did other samples of urine, absorb more oxygen than did the latter samples which were richer in ureine, and especially strong was this power of absorption in the urine of a pregnant woman. Urine which has been subjected for some length of time to a temperature of 70°–80° C. loses in a great measure its capacity of taking up oxygen, and when exposed to 90° C. for about half an hour it loses seventy-five per cent. of its absorptive power. It does not take up all at once all the oxygen which it is able to absorb, but does so with great avidity in the beginning, and gradually takes up less and less during equal periods of time; its capacity of absorbing oxygen is not wholly extinguished before a lapse of four or five weeks.

Ureine surpasses urea as regards quantity; thus far I have found that it is present in a quantity double that of urea. The greatest amount of ureine is contained in urine voided between 5 and 7 P.M. On July 11, 1900, I examined the urine of a diabetic woman and found six per cent. of ureine and only 2.1 per cent. of urea; the urine was voided about 6 P.M., specific gravity 1.025, total amount in twenty-four hours 1,250 c.c. The same woman gave me a sample of her urine on July 18th, at nine o'clock in the morning; this time I found only 2.3 per cent. of ureine. In the case of a pregnant woman (eighth month of pregnancy) I found on some days only one per cent.; on other days, especially when she had worked a good deal and had felt unusually well, I found almost three per cent. of ureine; on one occasion, June 10th, I had found only 0.6 per cent. of urea in a sample of her urine voided about noon. In the urine of an elderly man about sixty years old, I found four per cent. of ureine by volume; his urine was markedly yellow, of a rather strong odor, of a markedly acid reaction, and of a specific gravity of 1.030. The urine of a middle-aged man, thirty-five years old, suffering from polyuria, contained two per cent. ureine. This urine was voided on July 12th, at 8:30 A.M.; its reaction was markedly acid, its specific gravity 1.017½; the total amount of urine formed in twenty-four hours was 3,500 c.c.; the entire quantity of ureine excreted in twenty-four hours must have been at least 70 c.c., but was probably about 80–90 c.c., weighing 100–115 gm. A sample of urine from the same man, received on May 22d about 9 P.M., contained only 0.5 per cent. of urea, corresponding to 17–18 gm. of urea in twenty-four hours.

It is self-evident that the enumeration of even a greater number of isolated cases can afford no clew as to the clinical and pathological importance of ureine. The more gratifying must it be to us, as physicians, that at least in one respect the pathological significance of ureine is clearly established. It was to be expected *a priori* that the principal organic constituent of urine should be the true cause of those complex toxic symptoms which have been designated by the collective name of "uræmia," and which are quite frequently incidental to the puerperal state, after all the other organic and inorganic components of urine failed to account for these terrible toxic phenomena. A few experiments on rabbits have fully demonstrated the truth of this *a priori* conclusion. Several of these animals, each weighing over 1 kgm., have succumbed after three to eight hours from subcutaneous injections of 3½ to 4½ c.c. of ureine. For the present I shall give the results of only one of these experiments, the others closely resembling the one mentioned:

On July 22d, at 4:10 P.M., I injected subcutaneously into the dorsum of a lively black rabbit, weighing about 1 kgm., 3½ c.c. of ureine obtained from the urine of a pregnant woman in the ninth month of her pregnancy. Immediately after the injection the animal lay motionless for several minutes, evidently prostrated; in a few

minutes the rabbit made slowly a few steps; it seemed excited, but soon afterward was again prostrated; it tried to hide itself with the head resting against a pillar, the hind legs stretched out, and the ears flat; the respirations were 124 per minute (at 4:40 P.M.). At 5 P.M., the animal was still motionless, ears flat (as in cases of morphine poisoning), bladder and rectum relaxed. At 5:50 P.M. the animal presented a picture of complete prostration; it lay flat on its abdomen with the head flat on the floor, eyes closed, forelegs stretched out; it paid no attention to food placed by its mouth, did not stir when approached, but twitched once in a while; the respirations were 88 per minute, rather labored. At 6 P.M. the rabbit lay on its side; four minutes later it jumped up and had a short general convulsion, turned around slowly in a circle twice or three times. At 6:05 P.M. the animal lay on its right side, evidently *in extremis*. At 6:17 the respiration was very labored, difficult; now and then convulsive movements occurred. At 6:25 the respirations were 63 per minute. At 6:30 P.M. the animal's eyes were turned for one moment, the white of the eyes only being visible; the aspect of the animal was like one dead, except for slow, shallow respirations—a perfect picture of uræmic coma; now and then there was a spasmodic twitching of the legs. About 6:45 P.M. there were long-continued general convulsions with opisthotonos, the animal being stretched out in a semicircle from one end of the body to the other. After the convulsion the animal's respirations were 30 per minute, spasmodic; it opened and shut its mouth with each act of respiration, gasping for breath. At 7:06 P.M. it gasped at long intervals, and at 7:13 P.M. the animal was dead.

Lack of time forces me to conclude this paper, but before doing so I wish to state that ureine is the principal cause of the ammonical fermentation of urine, as without its presence urea cannot be decomposed into ammonia and carbon dioxide. Neither Pasteur's micrococcus ureæ, nor Leube's bacterium ureæ, nor any other micro-organism is able to change urea; in fact, in many respects urea is just as indestructible as iron, silver, or any other elements, for the strongest mineral acids do not decompose it, but simply combine with it. Only a temperature of above 130° C., perhaps 140° C., can split urea into ammonia and carbon dioxide. Ureine is therefore a ferment, which has a potential energy of at least 130° C. Without ureine all organic matter would become converted into urea, which would remain in nature without any use, and thus within a limited period of time all vegetation and animal as well as human life would cease.

Truly, this wonderful organic fluid deserves our closest attention and study, and I hope that my feeble efforts will give some impulse toward detailed researches, which may in the near future bring us to a full understanding of ureine and of its significance in relation to the science of medicine.

ROME, ITALY, PIAZZA MONTE CITORIO, 121.

Actual Experience with Wounds Inflicted by Modern Military Projectiles vs. Theory.—C. B. Nancrede disputes the conclusions of many of the recent writers on this subject, some of whom he claims "never set foot out of the country, and who never heard a bullet whistle." He details at some length his views as to theories of ballistics, and claims that while at short ranges deflection of the missile is not common, yet at the ranges at which most wounds are received it does occur much more frequently than is usually taught. He does not believe that results obtained from bullet wounds on the cadaver are the same as those produced by bullets shot into living tissues. It is a palpable mistake to suppose that a bullet fired into a dead body necessarily will produce the same effects as when living tissues are concerned, because the liquid fat of the medulla and cellular tissue becomes converted into a soft, solid mass by the loss of the body heat, the skin loses its elasticity as well as support afforded by the dense fasciæ rendered tense by muscular action, while other patent changes also occur. The lessened mortality in recent wars is due especially to the "first-aid" package with which the combatants are supplied. Without this, the results now would be practically the same as during the times before the packet was used. When distinct indications do not exist for meddling, the best primary treatment for modern ball wounds of joints is antiseptic occlusion and fixation, to be followed by antiseptic incision, exploration, removal of infected foreign bodies, fragments of bone, etc., and the maintenance of free drainage, when the occasion requires, not merely to meet a theoretical possibility which may never materialize.—*Toledo Medical and Surgical Reporter*, August, 1900.

Treatment of Fungoid Otitis Media.—A. Bonain secures local anæsthesia by means of a mixture of mentho-phenol cocaine, observes rigid antisepsis, and carefully cleanses the ear. The fungosities are then removed with snare, forceps, and curette. The field of operation is then re-anæsthetized and carefully dried. For cauterization he employs for small areas pure chloride of zinc, and for larger ones the same salt in ten- or twenty-per-cent. solution. Following cauterization the ear is irrigated with sterile water and lightly packed with iodoform gauze.—*Revue Hebdomadaire de Laryngologie*, July 21, 1900.

Does a Cerebral Abscess of Otitic Origin Ever Disappear Spontaneously?—Roepke says that the course of an otitic cerebral abscess is regularly acute or subacute. In many cases the pus opens into the ventricles or on the meninges after some days or weeks, and proves fatal. It is not rare, however, that the course is slow and that the purulent formation ceases, and the virulence of the infection may then be so light that a limiting wall will form. If the cerebral tissue surrounding the abscess is in nearly a normal condition, absorption can occur, although a case presenting exactly these conditions has never been observed. The membrane limiting the purulent focus may undergo calcareous degeneration, but it is not known whether the contents of the abscess undergo the same change or not. Cysts have been discovered in the brain of persons who have had purulent otitis, and certain authors have considered them as of otitic origin.—*La Pratique Médicale*, June 15, 1900.

Myotherapy.—Nathan Herman holds that massage is indicated: (1) For the removal of exudates or infiltrations, which it does by causing their absorption, to overcome stases, and to re-establish a more active local circulation; (2) for the after-treatment of fractures; (3) for the treatment of some forms of paralysis. Various forms of exercise are indicated for the correction of deformities, especially of the spine. Chorea, writer's cramp, cerebral congestion, indigestion, constipation, neurasthenia, anæmia, chlorosis, threatened or incipient phthisis, malnutrition, obesity, rheumatism are some of the disorders benefited by myotherapy. Gymnastics and athletics offer a vast field and an endless diversity of application, especially in the prevention of disease by the enhancement of vital resistance. Especially noticeable among the effects of exercise are the enlargement of the thorax and the increase in costal mobility, thus creating conditions which, if they do not preclude pulmonary diseases, at least render their attacks less noxious and fatal.—*Maryland Medical Journal*, August, 1900.

RECENT VIEWS ON THE EFFECTS OF ALCOHOL.

THE conclusion reached by Professor Atwater, as a result of experiments conducted by him last year to determine the effects of alcohol on the human system, that the substance taken in small quantities and under certain conditions is a food, has given rise to much and bitter discussion. The garbled accounts given in the newspapers of Dr. Atwater's findings are chiefly responsible for this state of affairs. Many of these journals proclaimed that the professor had proved alcohol as a beverage to be harmless, whereas in fact he went no further than to declare that it is oxidized in the same manner as any other food materials, and is transformed into heat and muscular energy. The experiments were not sufficiently prolonged to demonstrate what the effects might be upon the human organism of the habitual use of alcohol, nor was any attempt made to show that such use would be anything but harmful.

Another pronouncement on the same question has been recently made by the well-known Viennese clinician, Prof. Max Kassowitz, who asserts that the dogma concerning the nourishing and strengthening character of alcohol is one of the fatal errors of science. He holds the view that the majority of physicians take up an inconsistent position with regard to the use of alcohol, for the reason that while they are well aware of its dangerous and poisonous qualities, they nevertheless contribute to making permanent the false ideas concerning the value and effects of alcohol which are so generally disseminated. Kassowitz explains these inconsistencies on the ground that the teaching which considers alcohol a food because it is burned in the organism, has held its ground in spite of many disregarded newer investigations which have shown its indefensibility. He is therefore of the opinion that the assumption ascribing food properties to alcohol based on simple theoretical consideration is a grave scientific error, the removal of which is the most important preliminary condition to an effectual battle against alcoholism.

Dr. Hermann Blocher, of Basle, Switzerland, in an article in the *Internationale Monatsschrift für die Bekämpfung der Trinksitten* for April, comments very favorably upon Professor Kassowitz's utterances, and discusses the matter from the standpoint of physiological experiment. He refers to the investigations of Miura, which indicate that alcohol belongs to the same group of substances as glycerin, lactic acid, butyric acid, and so forth, which are indeed burned in the animal body, but which nevertheless are not fit, even to the smallest extent, to take the place of necessay food in the preservation of the body. Miura found that the addition of alcohol to the food before its being taken not only causes no diminution of the nitrogen output, and does not prevent the loss of body material (as is the case with the addition of sugar or fat), but that on the contrary the nitrogen output following this addition of alcohol may become yet greater than it had been without this addition.

Professor Atwater did not pretend in his experiments to prove the innocuousness of alcohol as a beverage, and it was due to the newspapers that such a belief was disseminated. Whether alcohol in small amounts and used with discretion is harmful has yet to be clearly proved.

CONSERVATISM IN THE TREATMENT OF APPENDICITIS.

THERE are several gradations of opinion on the question of when to operate in cases of acute appendicitis, and whether in all cases operation is the best treatment. Those who hold the most radical views believe that an operation should be undertaken as soon after the diagnosis is made as is possible, and various arguments and statistics are brought to bear in order to justify this attitude. Another group of observers believe that it is better to wait, especially in first or mild attacks, until there is some specific reason for operative intervention, of which several may exist when the patient is first seen, or may occur during the period in which the patient is under observation.

These observers are of the opinion that practically every case of appendicitis must sooner or later come to operation, if not on account of rapid development of threatening symptoms in the first attack, then during a recurrent manifestation or in the period of quiescence. We might add a third class of observers who are perhaps fond of being called "conservative," and who think that at least a fair proportion of cases of appendicitis result in recovery without operation, and that an appreciable number of patients do not again suffer from the disease.

Accumulating evidence, clinical and pathological, has very nearly driven this view of the matter into its last ditch, and it is hardly necessary to say more than that patients who have had appendicitis are never cured without operation, though they may be free from symptoms for a long time, and that one true attack of the disease, well marked enough to cause definite symptoms, invariably leaves the appendix in a condition which predisposes to subsequent attacks. The attitude of those who hold the views outlined in our second grouping have apparently a position of considerable justification, both from the evidence of the statistics of this disease and from the state of mind, usually present, which makes us assume that we ought

to relieve our patients with as little surgery as possible, as a matter of general principle. It is, however, undoubtedly a fact that the observers who are in a position to see and treat most cases of appendicitis are more and more coming to believe thoroughly that no case of the disease which results in recovery from an attack without operation is ever safe from another attack; in other words, as we have noted above, that true non-operative cure is impossible, and furthermore that in many instances the attacks increase in severity. It is quite true that many attacks can be tided over without operation, but this does not cure the patients, and what passes for conservatism is then too often timidity, indecision, or ignorance. Those who are most radical in their views form a group which is receiving constant accessions of men who are generally inclined to be aggressive in their advocacy of what they think is right, and are pretty successful in supporting themselves with logic and statistical material. Their position involves acceptance of the following statements: that appendicitis is always a grave and important disease; that it is never cured spontaneously; that the attacks are very apt to increase in severity; that the course of an individual attack involves several important elements of uncertainty; that there is no real non-operative treatment of the disease, though the symptoms can be mitigated and temporarily removed; and that operative treatment in competent hands, undertaken at the proper time, gives an exceedingly small mortality figure, which is unquestionably becoming still smaller and is unapproached by any form of non-operative treatment. The interval between the beginning of the attack and the operation is of the greatest importance in the prognosis, and no hard-and-fast rule can be made, but, in general terms, the more severe the attack the sooner should an operation be done. The "proper" time may be within two or three hours of the attack, and, according to the most radical, is rarely beyond twenty-four.

Now the views embodied in these statements seem at first sight extremely radical, and their diffusion and general acceptance are encountering a good deal of the inertia of "conservatism," but this is bound to be gradually overcome, and then the treatment of appendicitis will be looked upon purely as a surgical question, with the details of time and place to be decided promptly by the surgeon. When we reach this state of affairs, there will be a still further reduction in the mortality figures from this very important and common disease, fewer operations under desperate conditions, and much less chance of ventral hernias on account of necessarily large incisions in these same desperate cases. It will never be necessary nor wise to try to promulgate the rule that all cases should be operated upon within twenty-four hours of the beginning of the attack, for there are often cases which do not demand operation so immediately and so strenuously; though even under such circumstances the idea must not be to avoid operation altogether, but to choose the most favorable time at which to operate, either during the present attack in the period of quiescence, or when the next attack occurs, the last the less desirable. The true conservatism in treating patients with appendicitis consists in knowing when to operate upon a condition which sooner or later is certain to demand operative intervention, and in carrying out this intervention promptly and intelligently. It is not conservative to trust to luck that each particular case is not one in which surgery must be called upon for help, and to make an inefficient attack upon the symptoms, hoping that somehow the patient will survive.

LUSTIG'S PLAGUE SERUM.

A Bombay physician reports to the *Lancet*, of July 28th, a series of observations made on, and the results from the use of, Lustig's plague serum. The first series of observations lasted from March to November, 1898, and again from February to May, 1899. During the course of this period four hundred and three patients received the serum treatment and eleven hundred and ninety patients were treated by ordinary methods. The clinical effects of the serum were watched from day to day, and although in some very grave and advanced cases the patients ultimately succumbed, the immediate effects on the general condition of the patients were extremely well-marked, indicating either that the dose of the serum was too small, or that it was not strong enough, or that the treatment was commenced too late. On the whole, however, the improvement was quite perceptible and gratifying. When at the termination of these observations the results were tabulated, it was found that the serum-treated cases had a recovery of 38.2 per cent., whereas that in those not so treated was 19.5 per cent. only. The second series of observations was commenced in May, 1899. The object with which this series was started was to determine the statistical value of the serum, and hence it was resolved to conduct observations on one thousand cases of plague, five hundred to be treated with the serum and five hundred by ordinary methods, the latter acting as controls, and the cases were to be taken for treatment alternately in the order of admission and without any attempt of exclusion of any sort. But objection to this method of treatment was the preponderance of either moribunds or convalescents in either set vitiating the final results. It was, however, anticipated that in two such large sets of five hundred each these would equalize at the end, and thus no undue advantage would accrue to one side or the other. Further, in order to arrive at strict accuracy and to eliminate all errors, some standard had to be fixed as to what cases should be classed as moribunds and what as convalescents. It was therefore determined to fix the limit for the former at twenty-four hours, and all patients dying within twenty-four hours of admission were considered moribund; but as it was subsequently found that a large number died between twenty-four and twenty-seven hours of admission, twenty-seven hours was adopted as the standard. As regards convalescents all those that had gone over the acute stage of the disease and had a normal temperature or thereabouts, and had suppurating or suppurated open buboes, were considered convalescents.

The results of these observations were as follows: Up to the end of June 480 cases had been treated with serum and 480 cases had become controls. Of the serum cases 328 patients died, 152 recovered; percentage of recovery 31.67. Of the control cases 382 patients died and 98 recovered; percentage of recovery 20.42. The showing is even better if the moribunds and convalescents are eliminated from either series. The results then stand thus: Serum cases, 313; patients died, 189; recovered, 124; percentage of recovery, 39.62. Control cases, 297; patients died, 237; recovered, 60; percentage of recovery, 20.21, showing a difference of 19.08 per cent. in favor of serum. These facts are vouched for by the chief medical officer of one of the Bombay hospitals, and would appear to indicate in the clearest possible manner the value of the serum treatment of plague in general and of the use of Lustig's serum in particular.

News of the Week.

A School of Embalming is about to be established in London, "under American patronage," as the advertisement reads.

The International Language of the Future.—A writer in the *Tribune* states that Dr. Dietz, of the Berlin University, in a lecture before the Prussian Academy of Science, has declared his belief that English is undoubtedly the world language of the future. According to the London *Daily News*, the professor points to the wonderful diffusion of the English language through Great Britain and her colonies and the United States, a circumstance which in itself constitutes a great claim to a still more pre-eminent position among the languages of the world. But, apart from its political prestige, English, thinks the professor, is remarkably adapted by its very structure to be the *Weltsprache*. It has freed itself from all superfluous ballast of declensions and conjugations and genders. By its fusion of the Germanic and Latin elements it represents "two principal streams of culture." "The young Englishman," says Dr. Dietz, "unconsciously from early childhood amalgamates valuable elements of cultivation dating back one thousand years in his Germanic-Roman mixed speech which every other nation only acquires with great pains and at great expense."

Quarantine in the Philippines.—Passed Assistant Surgeon Perry, chief quarantine officer for the Philippine Islands, has recently completed an inspection of Philippine ports of entry with reference to quarantine service. As a result of the investigation he recommends that as vessels come direct from Hong Kong to Iloilo, and the distance from there to Manila is thirty-six hours, a small station, with barrack accommodations for one hundred people, be equipped at Iloilo as soon as practicable. This station would be available for a great number of vessels from the neighboring island ports. He also recommends the establishment of a small floating and disinfecting plant and barrack accommodations at Cebu, as a station there would be convenient for the disinfection of boats coming from the groups of islands to the east and south of Luzon. It may also be necessary to have a station at Zamboanga on the island of Mindanao, as it is purposed to have ships from Singapore and Australian ports call there. Assistant Surgeon L. D. Fricks has been detailed as quarantine officer at Iloilo, and Assistant Surgeon H. A. Stansfield at Cebu.

The University of St. Andrews has received a gift of £20,000 from the Marquis of Bute to establish a chair of anatomy.

The Hospital Ship "Maine."—The Anglo-American hospital ship *Maine*, which rendered such effective service in the Boer war, both as a hospital station at the Cape and as a transport for sick and wounded soldiers to Netley, has been sent to China. She arrived at Hong Kong last Saturday, and on Friday of this week proceeded to Wei-hai-Wei.

Tuberculosis in Hawaii.—The Honolulu health reports show a progressive increase in the death rate among the Japanese and native Hawaiians on the island of Oahu. The greatest increase is in the deaths from tuberculosis, and the board of health is discussing measures for restricting the immigration of consumptives, of whom there are many coming to the island because of its climate.

Plague in Nicaragua?—A report from Managua, dated August 1st, states that some kind of dangerous epidemic is causing the death of rats and pigs in that place. Hundreds of those animals are found lifeless in the streets and vacant lots. The number of pigs that have died from the unknown malady is very large. The rats are also very numerous, and the great mortality among them is evidently connected in some way with that among the hogs. A sanitary commission has been formed which is endeavoring to discover the cause of the epidemic and to put a stop to its ravages, lest it should prove to be the bubonic plague and attack the population.

Leprosy in the Philippines.—Surgeon-General Sternberg has received a report from Major Guy L. Edie, president of the board of health in Manila, stating that the board of health is considering a plan to segregate all the lepers on one island, where hospitals and other suitable buildings can be erected for their care. The report states that leprosy was introduced in the Philippines in 1633, when the Emperor of Japan sent one hundred and fifty lepers to the islands. Since then the number has increased until the estimate is that there are thirty thousand lepers in the archipelago, largely in the Vasayas. In a recent inspection of Manila, one hundred lepers were found concealed in various houses, while many others escaped to the country.

The Russian Medical Service in China is said to be better than that of the other European nations. The number and good organization of the Russian ambulances should afford, it is said, an object lesson for the other powers. At Moscow twelve new military medi-

cal corps have just been organized, and they will shortly start for the East. Each of these corps consists of four physicians, four Sisters of Charity, and eighty-two nurses.

Carbolic Acid has been officially declared a poison in Great Britain, and its purchase is now hedged about with the same formalities, meant to be deterrent, as that of other deadly drugs. Special provision has, however, been made to facilitate its sale for agricultural purposes.

A Chilian Medical Congress is announced for December of the present year. This ought to be an additional reason for the postponement of the Pan-American Medical Congress to some more convenient season than the Christmas-tide.

The Bubonic Plague in Glasgow.—Several cases of plague have been discovered in Glasgow, and the families of the sufferers, as well as those of persons who have come in contact with the sick—forty families in all—have been quarantined. Up to Wednesday of this week there had been five deaths. The disease was imported in a ship recently arrived from the Orient.

A Coroner's Diagnosis.—A physician in Philadelphia who attended a boy six years old, who died in convulsions, believed the symptoms to be those of hydrophobia, and so informed the coroner. There was a history that the child was bitten by a dog twenty-six days previously, and that he died in convulsions resulting therefrom. The coroner instructed the jury that he discredited the hydrophobia theory, and that his opinion was that death was due to the excessive heat, causing the convulsions. The jury found a verdict accordingly.

No Base Hospital for China.—With a probable recall of some of our troops in China, the large base hospital that was projected by the government at Nagasaki, Japan, has been abandoned, and the wounded and sick from China who would have gone there will be brought to San Francisco and treated in the general hospital at the Presidio. The physicians and nurses who had been ordered to Nagasaki will remain in San Francisco until it is definitely decided that their services will not be required in China or the Philippines.

A Royal Lady's Doctor's Bill.—A report from Honolulu states that Dr. Charles E. English, who was ex-Queen Liliuokalani's physician for about two years, has sued her for $5,000. He declares he gave up all his practice to attend her, for which he was to receive $300 a month, with a bonus of $5,000 should she part with his services. In case she received compensation for the crown lands he was to get $30,000. In July, he says, she suddenly told him that his attendance was no longer required, and refused to pay the $5,000.

The Rôle of the Mosquito in Filariasis.—We recently noted the discovery by Dr. George G. Low, of London, of the filaria sanguinis hominis in the proboscis of the mosquito, and his deduction from this that man might receive the parasite by direct inoculation instead of by drinking water in which the worms had been deposited on the death of the mosquito. This discovery has been confirmed by the members of the expedition of the Liverpool School of Tropical Medicine now at Bonny in equatorial Africa.

Cholera is reported to be prevailing to an unusual extent in Bombay, the present epidemic, according to *The Daily Mail* of London, being one of the worst on record. The bubonic plague is for the time being quiescent.

Anti-Alcohol Teaching in the Public Schools.—The school superintendent of Cincinnati has forbidden the use of colored pictures showing to a greatly exaggerated degree the effect of alcohol upon the mucous membrane of the stomach and upon other organs. He says the pictures are unæsthetic and fill the minds of the children with unpleasant impressions, and give them false notions which will react harmfully on them in the future. He favors impressing upon the pupils the benefits of temperate eating and drinking, and not dwelling upon the horrors of an intemperate use of alcohol. He says he is in favor of giving instruction in hygiene and preventive medicine, and suggests that the city health department issue circulars and papers, which shall be used as the teachers see fit. These will show how contagions are to be prevented, and in general give pupils an idea of how best to preserve their health.

Second Attacks of Typhoid Fever.—Dr. T. J. Maclagan, writing in the *British Medical Journal* regarding preventive inoculations for typhoid fever, says that the foundation of the treatment is a hypothesis which is inconsistent with fact. The idea is that, as one attack of typhoid gives immunity from a second, temporary if not lasting immunity might be acquired by inoculation with an attenuated dose of the poison. But one attack of typhoid does not give immunity from a second, he says. Second attacks of typhoid are as common as, by the ordinary doctrine of chances, they ought to be; more common, for instance, than second attacks of pneumonia, in about the same proportion that first attacks are more common. If one attack of the fully developed disease does not give immunity, he concludes, inoculation with an attenuated dose of the poison can scarcely be expected to do so.

Insanity in the Philippines.—Dr. Charles H. Latimer of St. Elizabeth's Asylum, Washington, has been commissioned by the government to go to the Philippines to study and report upon the effect of the climate of those islands upon the brain.

Deaths from Rabies in New York.—A boy thirteen years old died a few days ago in the Harlem Hospital of hydrophobia. He was attacked while playing in the street by a dog which bit his nose off. The first symptom of rabies appeared seventeen days later. It is stated that this is the seventeenth death from rabies reported in this city during the past five years.

Trouble on a Hospital Ship.—It is reported that there has been serious trouble on the hospital ship *Relief*, now at Nagasaki. Thirteen men in the en-

gineers' department and several officers are said to have struck. They are also said to have expressed the determination not to sign new service contracts when those now in force expire. The first officer of the *Grant* has been ordered to the *Relief* as master.

An Obstetrical Fraud.—A French contemporary relates an instructive story of a young physician who was visited by a woman presenting the external signs of pregnancy. She engaged him for the approaching confinement and left. A few months later the physician was summoned to his patient, to find the infant not only born, but washed and dressed. He was gently chided for his slowness in responding to the summons, and was requested as a particular favor to call at the registration office for the purpose of registering the birth. Anxious to re-establish himself in the good graces of his patient, the physician did as requested, leaving the house without examining either mother or child. We may judge of his surprise and dismay when, some time after, he was prosecuted by the state for aiding and abetting in a fraud by having made a false declaration as to the birth of a child. It turned out that his patient had not been pregnant and consequently had not borne a child; but had presented her physician with a supposititious one and made him a guileless partner in her attempt fraudulently to acquire some property. Fortunately for the young man, M. Brouardel interested himself in his case, and the prosecution was dropped.—*The Medical Press.*

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 25, 1900. August 20th.—Passed Assistant Surgeon L. L. von Wedekind ordered to temporary duty at the headquarters of the marine corps, Washington, D. C., August 22d, and then to the *Richmond*. August 24th.—Medical Inspector J. R. Waggener transferred from the naval hospital, Cavite, P. I., to the naval hospital, Yokohama, Japan, for treatment. Surgeon G. Pickrell detached from the naval hospital, Yokohama, Japan, and ordered to the Cavite naval station. Surgeon O. D. Norton detached from the *Monocacy* and ordered to duty with the marine regiment in China. August 20th.—Pharmacist S. W. Douglass detached from the *Massasoit* and ordered to the Key West naval station immediately.

The Hospital Charges in South Africa.—A Mrs. Chamberlain, sister-in-law of the British Secretary of State for the Colonies, has contributed an interview to a London paper in which she declares that the charges regarding the mismanagement of the military hospitals in South Africa, recently made in Parliament, are literally true. She says that hospital supplies were intentionally withheld, and also expresses a poor opinion of the surgeons, saying that "with few exceptions the army doctors are a low class of men. Those in South Africa neglected their patients. Six cases of drunkenness among army doctors came under my observation. After these people had come into contact with the police they were sent home in charge of invalids." Possibly Mrs. Chamberlain, who had been for several months in South Africa, was one of the atoms in the "plague of women" concerning which Mr. Frederick Treves spoke so feelingly. In that case her animosity against the army surgeons receives a ready explanation.

Danger of Yellow Fever from Cuba.—Surgeon-General Wyman of the Marine-Hospital service has recently received a report from the chief quarantine officer at Havana, that during the month of August, up to the 26th, there had been two hundred and four cases of yellow fever reported at Havana, and thirty-four deaths. Many of the cases were very mild. There were eleven new cases August 27th. On account of the mildness of the cases and their short duration the surgeon-general has notified the various quarantine stations on the Atlantic and Gulf coasts to use particular care to prevent an importation of the disease.

Obituary Notes.—Dr. William B. Waterman died at his home in Brooklyn on August 21st, after an illness of several months' duration. He was born in Brooklyn in 1862 and was graduated from the Medical Department of the University of New York in the class of 1887, taking the Mott medal.

Dr. Ernst Schmidt, of Chicago, died on August 25th. He was born in Bavaria in 1830, and was a graduate of Würzburg in 1852. Soon after graduation he came to this country and settled in Chicago, where he practised for over forty years. He was connected with the Alexian Brothers' Hospital and also with the Michael Reese Hospital.

Dr. Ferdinand E. Chatard, of Baltimore, died at Atlantic City on August 27th. He came of a line of medical men, his father and grandfather both having been surgeons of prominence. He was educated at Mount St. Mary's College, Emmittsburg, and was graduated in medicine from the University of Maryland in 1861. After a period of study abroad he returned to Baltimore and became associated with his father in practice. One of his brothers is the Roman Catholic bishop of Vincennes, another is a physician in Washington.

Dr. Frank Stephen Milbury died at his home in Brooklyn on August 29th, at the age of forty-three years. He was born in New Brunswick, and first turned his attention to dentistry, practising in Nova Scotia and later in the City of Mexico. He then studied medicine and was graduated from the Cincinnati College of Medicine and Surgery in 1888. After a period of post-graduate study in Europe, Dr. Milbury entered upon practice in Brooklyn. He was laryngologist and otologist to the Bedford Hospital and assistant at the New York Eye and Ear Hospital.

Rev. Dr. John S. Breckinridge, superintendent of the Methodist Episcopal Hospital, Brooklyn, died on August 28th at Stamford, Conn. He was about sixty-three years old, and was born in Pennsylvania. He was graduated from Wesleyan University in 1861. In 1887 he was appointed superintendent of the Methodist Episcopal Hospital, a position he held up to the time of his death.

Progress of Medical Science.

The Medical News, August 25, 1900.

The Abortive Treatment of Acute Mastoiditis.—James F. McKernon says that when a case comes under observation, if there is not sufficient drainage of the middle ear the perforation made by nature in the drum membrane must be enlarged, and if the upper portion of the middle ear or attic is infected this incision is extended upward, opening Shrapnell's membrane, and still continued outward and backward through the tissues of the superior canal wall, thus making what has sometimes been called an internal Wilde's incision. This done, the patient is placed in bed and kept absolutely quiet on a fluid diet; an ice coil is applied snugly over the mastoid process, a free purgative is administered, and the canal is irrigated every two or three hours (depending upon the character of the discharge) with a warm solution of bichloride of mercury, 1-4,000. The coil is left in position for twenty-four hours, and at the end of this time we usually find upon its removal much less tenderness than had existed before, and if all swelling has not entirely disappeared it has markedly diminished. Usually in from thirty-six to forty-eight hours convalescence is established and the danger of mastoid involvement is over. The author is strongly opposed to the application of moist heat to the mastoid process of a patient suffering from acute middle-ear disease.

Medullary Narcosis during Labor.—S. Marx reports several cases of lumbar cocainization employed to mitigate the pains of parturition. He says the report is only preliminary, for the cases are too few to warrant any wide deductions as to the ultimate value of this method. As far as he can form conclusions from the few experiments he has made, he says he feels warranted in stating that in lumbar cocainization we have a method which is of the greatest value in producing analgesia, which checks almost entirely the pains of labor without, so far as personal experience goes, the least danger to mother or child. "It is very astonishing and awe-inspiring to those of us who have seen many labors and heard the agonizing and maniacal shrieks of these poor women, to see the parturient, under the influence of cocaine, lie quietly in bed, feeling only some indescribable sensation, but without pain, bearing down when told to, and giving birth to her child without her knowledge, and only cognizant of the fact when the first cry of the new-born is heard." The puncture is made between the third and fourth or fourth and fifth vertebræ, the point of the needle being pushed slowly and gently downward until the spinal fluid is seen running out. An injection is then made of ten minims of a solution representing gr. $\frac{1}{6}$ of cocaine.

The Construction and Management of Small Cottage Sanatoria for Consumptives.—By Arnold C. Klebs.

Co-operation of the Public Schools in Teaching "Good Teeth, Good Health."—By Richard Grady.

Tuberculosis and Modern Methods for its Prevention.—By H. H. Vinke.

Boston Medical and Surgical Journal, August 23, 1900.

Hysterectomy for Myoma in America.—Ernest W. Cushing points out the principal contributions of Americans to this branch of surgery. Up to 1895, in the transition period, there was a mortality of 13.8 per cent. At present, in the hands of good operators, there is often a series of sixty or seventy-five or more cases without a death. The change of methods in performing hysterectomy for myoma may be briefly summarized as: (1) Entire abandonment of the extra-abdominal treatment of the stump by serre-nœud or rubber ligature; (2) the wide trial and substantial rejection of vaginal hysterectomy, as an operation of election in cases of myoma and salpingitis; (3) the establishment of indications for the retention of the cervix uteri, as compared with total extirpation of the uterus; (4) the adoption of a method substantially the same by most operators; (5) the disuse of drainage wherever possible; (6) the common employment of the operation by general practitioners operating in the small hospitals which are springing up in all towns of three thousand or more inhabitants. This generalization is at present a disadvantage, but by competition and training tends to the diffusion of good surgery throughout the country.

Repeated Ectopic Gestation in the Same Patient, with Operation in Each Case.—Malcolm Storer and M. T. Thurber report the case of a young woman, who in December, 1898, was operated upon by the former for ectopic pregnancy, and the left tube and ovary were removed. In May, 1899, Dr. Thurber again found that the patient had an extra-uterine pregnancy, and Dr. Storer performed a second operation. The tube was removed, but most of the ovary was left in place and stitched to the stump of the tube. In the first operation, an attempt was first made to use the vaginal route, but this had to be abandoned on account of free hemorrhage. In general terms, the author would confine the vaginal operation to women with large pelves, yet even in them, should there be urgent symptoms of active hemorrhage, he would personally prefer the abdominal route, as the source of bleeding could more easily be found and controlled. Should the operator prefer to begin by the vaginal route, he would be wise to have everything ready for a cœliotomy in case he should find it necessary to abandon the vagina in a hurry.

The Mortality of Hysterectomy for Fibroids.—F. H. Davenport points out that the causes of danger in case the tumor is left alone are: (1) hemorrhage, which may become a source of danger, no matter what the size of the tumor; (2) pressure from a large tumor causing disease in other organs; (3) anæmic necrosis of a part of the tumor; (4) the development of malignant disease in connection with the fibroid. The author has done nineteen hysterectomies for fibroids. Two of the patients died; these had large tumors which presumably could have been successfully removed if taken earlier. In addition to these two cases, there were two of malignant degeneration, three of anæmic necrosis, one of the latter presenting malignancy as well. Therefore out of nineteen cases there were six in which life was threatened by the presence of the growth. The author strongly advises the removal of fibroids if symptoms are present.

Immediate Repair of Perineal Tears.—E. S. Boland says that if carefully carried out the immediate operation of suturing ought to give ninety per cent. of successes. An anæsthetic is not usually necessary: the value of the prompt restoration of the perineal body does not depend wholly on the after-results, but also on the influence it exerts to minimize the risks of septic infection in the puerperium. To illuminate the vagina, the head mirror of the laryngoscope with head-band attached will be absolutely satisfactory, and a neighbor or the patient herself can hold the lamp, thus obviating the necessity of an assistant, which in poor families is a consideration.

Medicine as a Science and Medicine as an Art.—By Philip H. Pye-Smith.

The Philadelphia Medical Journal, August 25, 1900.

A Contribution to the Significance of Koplik's Spots in the Diagnosis of Measles.—Jose L. Hirsh reports seven cases, one in a negro, in which a diagnosis of measles was made or confirmed by the observation of Koplik's spots, and he formulates the following conclusions: (1) An eruption limited to the buccal and labial mucous membrane and characterized by the presence of an irregular red spot with a bluish-white centre, is always present in beginning measles. (2) These spots are present for twelve hours to five days before the cutaneous outbreak. (3) The number of these spots bears no relation to the severity of the attack. (4) These spots will be found in no other condition of health or disease.

The Psychoses of the Menopause.—John B. Chapin says that of 8,320 women admitted to insane asylums in 1899, 188, or 22 in 1,000, were stated to have become insane at the menopause. Many women who are melancholy or threatened with insanity at the menopause have had serious neurotic or mental symptoms at the age of puberty. He says it can be stated as a clinical conclusion that women who become insane at the menopause as a rule possess a neurotic and mental heredity, or have already suffered from recurrent insanities during the menstrual life, and are rendered suitable and peculiarly liable to a fresh attack at any crisis in their lives.

Journal of the American Medical Ass'n, August 25, 1900.

Keratitis Bullosa.—E. O. Sisson reports a case of this rare affection, which is usually secondary to blindness caused by corneal cicatrix, iridocyclitis, increased tension, etc. According to Fuchs, the lymphatic stasis of glaucomatous eyes produces an interstitial œdema of the epithelium, which tends to the production of vesicles, etc. The continual irritation of the corneal epithelium alters the nutrition of the cells. The usual treatment of opening the bullæ and touching the raw spots with nitrate-of-silver solution was first adopted. This, together with atropine, was fruitless.

Iridectomy was then done under cocaine. At first this promised success, but suddenly new bullæ appeared and the eye was enucleated, a procedure which the patient had pleaded for from the first. In this case the condition, which had existed for a year, was secondary to cataract and complete posterior synechia of the iris.

Chemical Factors in Interstitial Gingivitis.—W. L. Baum says that since the gums at times take upon themselves the function of excretion, they are peculiarly apt to be affected by chemical action. The metals and phosphorus all produce, by their excretion through the gums, conditions of œdema, which are predisposing factors to interstitial gingivitis. Among vegetable alteratives having a like action are colchicum, guaiac, salicylic acid, sarsaparilla, and pilocarpine. A culture-medium is furnished by the œdema produced. In a case of mercurial stomatitis examined, evidences of inflammation were found in the gums, bacteria being absent, and it was thought to be due to the chemotactic influence of the mercury in process of excretion. Bacteriological invasion is secondary to an endarteritis obliterans, producing an anæmic infarct, which either undergoes absorption or becomes necrotic.

Cerebral Localization.—Sydney Kuh speaks of cortical localization, cerebral centres, distribution of motor centres, etc. The points in differentiating Jacksonian from idiopathic epilepsy are: the spasm is limited in the beginning of the attack; loss of consciousness occurs late, if at all; the epileptic cry, fall, and biting of the tongue are usually absent; post-epileptic coma is slight, of short duration, or entirely absent; and in the *état de mal* there is no rise of temperature. The history and age aid. The diagnosis of corpus callosum lesions is usually impossible. The signs of importance are enumerated. Temporal lobe, basal ganglia, alternating hemiplegia, etc., are considered.

The Constitutional Treatment of Interstitial Gingivitis.—J. H. Salisbury says that besides metallic and other drugs, auto-intoxication plays a part in pyorrhœa alveolaris, atrophic changes being due to poisons circulating in the blood. Successful treatment depends upon the discovery of the toxæmia by which the condition is caused. The indications to be met are: (1) to stimulate the eliminating organs; (2) to fortify the system against the action of the poison; (3) to prevent the formation of the poison.

Local Treatment of Interstitial Gingivitis.—M. H. Fletcher quotes Talbot to the effect that the exciting cause of gingivitis is tartar, and believes with Carpenter that without a locally exciting cause the disease would not exist. He makes an acute, a chronic, and a sloughing stage. He advocates soft-wood toothpicks, stiff brushes, and tooth-powders containing no gritty substances.

Anæsthesia.—D. H. Galloway reports a case which illustrates the value of nitrous oxide as an aid to anæsthesia when ether or chloroform is employed.

How to Place Lenses Before the Eyes so that Distance of their Respective Anterior Foci Shall be the Same.—By Mark D. Stevenson.

The Bacillus of Philippine Dysentery.—Extract of a report by R. P. Strong and W. E. Musgrave.

The New York Medical Journal, August 25, 1900.

On a New Method of Operation for Exstrophy of the Bladder.—Carl Beck reviews the various procedures devised for repair of this most distressing condition, and gives a plan of his own recently modified which has served him well. The disadvantages of implanting the ureters in the sigmoid flexure are discussed, and while intestinal implantation approaches more nearly the ideal *restitutio ad integrum*, there are severe risks attending it. His own autoplastic method for restoring the retentive power by an anterior muscular wall is described, and cases are cited, showing how a small bladder was secured and protected by a firm muscular layer.

A Case of Murphy-Button Anastomosis.—John von Aesch relates an instance of abdominal injury with attempt at suture and subsequent insertion of the button. The features are: long delay, very dirty gut, time lost in vain attempt to suture, and passage of the button on the eleventh day, bringing with it a large intestinal worm which had been caught in the trap-like opening of the button.

A Case of Cyst of the Epiglottis.—W. L. Bullard relates a case of this rare condition. After incision of a filbert-sized cyst on the anterior surface of the epiglottis and touching with strong silver solution, there was recurrence. After a second incision with discharge of gelatinous fluid, and touching the interior of the sac with fused chromic acid, cure was permanent.

The Lancet, August 18, 1900.

The Hot-Air Treatment of Eczematous, Gouty, Rheumatic, and Other Affections.—David Walsh describes the apparatus employed in the application of hot air. The method is likely to do good in painful nervous affections, many painful and stiffened joints, anæmia, Bright's, eczema, rheumatism, gout, etc. A typical case of gonorrhœal rheumatism treated with good results is detailed. It is here shown that cardiac complications need not necessarily contraindicate the application of the Tallerman treatment.

Measles, German Measles, and the "Fourth Disease."—Robert Craik relates the history of several cases. In Case I. a scarlet-fever-like rash with very little fever, illness, or desquamation was present in 1899. In March, 1900, the patient had measles, and in May, 1900, she had German measles. Cases II., III., and IV. proved to be the first of an epidemic of German measles. The reasons for not regarding the cases as scarlatina are given.

An Unusual Case of Scarlet Fever.—A. J. Rice Oxley relates an instance of scarlatina in which, six days after desquamation began, and two days after the patient first sat up, the cervical glands began to swell. Five days later there was fever (103 F.), and ecchymoses began to form on various parts of the body, and then large extravasations followed by death. The reporter is at a loss for an explanation.

Preliminary Rashes in Measles.—J. H. Thursfield records a case and speaks of scarlatiniform rashes which were present in five out of seven cases seen. In four they were the earliest manifestation of measles, Koplik's spots not being found. The scarlatiniform premonitory eruptions are apt to mislead, especially since text-books do not as a rule mention them.

Münchener medicinische Wochenschrift, August 7, 1900.

The Pathogenesis of Gout.—O. Hager discusses the various theories as to the causation of this disease, and contrasts the views of recent continental observers with those of the English writers. Garrod's theory is that owing to dietary excesses, exposure, exertion, injury, etc., an attack of gout may be produced, which consists in the deposit of uric acid in the form of a urate in the joints or the surrounding tissues, in anomalous forms also in the internal organs. Through the attack the blood is relieved of the excess, and the deposit in the joints appears as a sort of safety-valve for the escape of the surplus. Luff regards as materia morbi the quadri-urate of soda, and explains the formation of uric acid in two ways. In health it is formed in the kidneys, probably from urea and glycocin, and is immediately excreted by the urine. If as a result of some functional or organic disturbance this process is impeded this substance is taken up by the circulation and forms the supply which furnishes the gouty deposits. In diseases which are accompanied by leucocytosis uric acid may originate in the nuclein of the leucocytes in the spleen and possibly in the entire body, but this is properly taken care of by the kidneys, which are supposably in a normal state, and hence no gouty deposits are found. These views seem untenable to the author, who advocates the following theory: Under the influence of heredity, the lymphatic constitution, or intoxication of some sort, and sometimes with-

out any recognizable cause, a state of faulty metabolism is inaugurated. This consists in the retention in the body of a considerable quantity of nitrogen, which does not enter into the formation of new albuminous bodies. These retained substances, which are not demonstrable as uric acid and which comprise such alloxur bodies as adenin, circulate in the blood and eventually produce necrosis of certain tissue cells. These necroses constitute a decomposition which leads to the formation of alloxur bodies and an increased amount of uric acid in the blood, which is deposited in the damaged areas, and so the gouty circle is fulfilled.

Nervous Disturbances in the Domain of the Brachial Plexus in Angina Pectoris.—L. Loewenfeld describes the accessory nervous disturbances accompanying angina pectoris and illustrates by the citation of a case history. The brachial symptoms may be grouped into three classes: disturbances of sensibility, of motility, and of vasomotor control. As regards their bearing on the angina it is to be noted that they may be entirely absent, but it is more often the case that they are concurrent with the cardiac seizure, though there is no definite relationship between their intensity and the severity of the disease proper. Sometimes it is observed that the accessory symptoms precede the main attack, and in others that they considerably outlast it. This is especially true of the sensory manifestations, parasthesiæ, etc. Finally the brachial neuralgia may appear to be entirely unrelated to the cardiac disease and run an independent course. Under these conditions there seems to be no common causative agency for the two, but they mutually aggravate each other.

A Case of Death from Starvation.—Hartmann describes the post-mortem findings in a man aged seventy-three years, who was allowed to die through lack of food in the almshouse of a small village. The evidence of the manner of death lay in the emptiness of the alimentary tract, the presence of old hard fecal masses, the loss of body fat, the anæmia of many organs, and the absence of any other cause, as well as the testimony of witnesses which showed that for twelve days he had received no food.

Berliner klinische Wochenschrift, August 6, 1900.

Idiopathic Evanescent Clouding of Consciousness.—Placzek reports two cases of temporary mental aberration which are interesting from a forensic point of view. The first concerns a woman aged about forty years, who without warning became entirely irrational in language and action for a period of six hours, after which she returned to the normal and had no recollection of the time that had elapsed. The other case is that of a man, and is much of the same type, except that in this instance the recovery took place just as suddenly as the onset of the trouble, while in the former it took several hours for a clear realization of events to be re-established. In their causation the author thinks that seizures of this sort are referable to circulatory disturbances in the cortex, and calls attention to somewhat similar phenomena observed in those resuscitated after strangulation by hanging, in which the main effect is the compression of the carotids. It is of great importance from a medico-legal standpoint to recognize the possibility of such a loss of emotional control, which it appears may occur quite independently of any epileptic, hysteric, traumatic, or hereditary taint.

A Contribution to the Bacteriology of Whooping-Cough.—G. Arnheim corroborates the findings of Czaplewski and Hensel on the ground of forty-four cases of the disease and three autopsies studied by him. In the sputum of these patients and in two of the bodies he was able to find and grow in pure culture the Czaplewski-Hensel bacillus, which is described as occurring singly or in chains, the individuals appearing to be divided in the middle owing to the fact that only the two poles take up the stain. Control experiments on patients with other pulmonary and bronchial diseases gave negative results. Taken in connection with the observations of other authors, the number of cases in which this bacillus has been isolated is now sufficiently large to leave little doubt as to its specific nature, and although experiments on animals have not been successful, still the requirements of Koch's law as to constancy of species and location and the possibility of pure culture have been complied with.

Deutsche medicinische Wochenschrift, August 8, 1900.

A Typhoid-Like Disease Caused by a Bacillus Resembling that of Typhoid.—Schottmüller, in making bacteriological tests of the blood of fifty typhoid patients, was able to cultivate the specific bacillus in eighty per cent. of the cases. One of these, however, while running the typical course of a rather mild typhoid, yielded cultures of a bacillus which differed so markedly from the normal that there is no doubt in the author's mind that it is a separate variety. In its cultural characteristics it corresponds closely to the Koch-Eberth bacillus, but in addition to the usual properties it possesses the entirely irregular ability to produce fermentation in sugar bouillon. The patient's blood gave no response whatever to the Widal reaction, but caused the agglutination of cultures of its own atypical bacilli even in the dilution of 1 : 100. The converse of the experiment was then tried and the serum of four typhoid patients that reacted with typhoid bacilli at a dilution of 1 : 100 allowed to act on the abnormal bacilli, with the result that even at 1 : 20 only one specimen caused clump formation. While the regularity with which the typical Widal reaction is obtained is sufficient evidence of the rarity of this form of the disease, the author thinks that those not altogether uncommon cases in which the reaction never appears are explicable on this ground, and recommends that in all such a bacteriological examination of the blood be made.

A Contribution to the Study of Polyneuritis Puerperalis.—M. Minkiewicz describes a case of multiple neuritis beginning in the latter half of pregnancy and undergoing sudden exacerbation immediately after labor. Neither the history nor the physical examination shed any light on the causation of the disease, which first involved mainly the lower extremities and later became seated in the arms. The labor was a perfectly normal one, and there were no signs of septic infection either intra- or post-partum. Medication seems to have had no effect whatever on the course of the trouble, which lasted for five months, at the end of which time the patient made an apparently perfect recovery.

Operations on the Prepuce.—S. Bernheim draws the following conclusions from the experience of a long practice: (1) The prepuce is an organ often presenting congenital or acquired malformations of very irregular form. These malformations, annoying during infancy, may become the point of departure in the formation of bad habits (masturbation) or of infirmities (retention or incontinence of urine). During adult life they constitute an impediment to sexual congress and favor all kinds of infectious inoculations (chancroids, syphilis, blennorrhagia, epithelioma, tuberculosis). At times, too, they are the direct cause of sterility. It is, therefore, well to examine this anatomical organ in all new-born. Preputial adhesions may be ruptured, the preputial orifice may be dilated, or a piece excised so as to permit liberation of the glans. Circumcision is the most salutary procedure, and useful from different moral and material points of view.—*Journal de Médecine de Paris*, August 12, 1900.

Pathology of the Initial Sclerosis in Syphilis.—Ehrmann, of Vienna, has proved, by the artificial injection of the blood-vessels and lymphatics in chancre, that the contagion advances principally by way of the lymphatics coming off from the region contaminated. The virus in spreading in the lymphatics produces an irritation in the network of blood capillaries surrounding the lymphatics, and causes the latter to become filled with lymph cells destined to combat the virus. In consequence of these observations the writer has practised upon the chancre electric diffusion with corrosive sublimate. In this way he has prevented the production of secondary symptoms in some cases treated during the first fortnight following contagion and before the appearance of regional adenopathy. Electric diffusion is a very simple procedure applicable to all cases seen early. —*Le Bulletin Médical*, August 11, 1900.

Treatment of Neurasthenia.—De Fleury, in a report upon the treatment of nerve prostration, comes to these conclusions: (1) In the genesis of the symptoms of neurasthenia it seems proven that the brain initiates and that the other symptoms, and notably the gastric symptoms, are secondary. The gastric state does not cause the mental, but it aggravates and keeps it up. (2) The brain is the origin of all the symptoms, but not the brain as an organ of thought. The fixed idea is not, as in hysteria, a generator of symptoms. (3) The fatigue of the nervous centres engenders a general functional paresis which has its reflec-

tion in the feelings. Treatment must be based upon this conception.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, August 9, 1900.

Bulletin of Johns Hopkins Hospital, July and Aug., 1900.

A Comparative Study of Some Members of a Pathogenic Group of Bacilli of the Hog Cholera or Bacillus Enteritidis (Gaertner) Type, Intermediate between the Typhoid and Colon Groups.—Harvey Cushing describes a bacillus, the bacillus O, which is intermediate between the typhoid and colon groups, the clinical significance of which, as a definite type, has been much neglected. It possesses the morphological and motile properties of Eberth's bacillus, but differs from this organism in the fermentation reactions, producing gas in the presence of glucose and other more easily fermentable carbohydrates. Its chief characteristic difference from the bacillus of Escherich rests upon the fact that fermentation in various media made from milk does not produce sufficient acidity to precipitate the casein, but, on the contrary, the acid production is but a transient process and is followed in the presence of air by a prompt (two to three days) and distinguishing alkalinization of the media, which furnishes a ready means of differentiation from both the typhoid and colon type. The author demonstrates that the definiteness of the serum reactions, pathogenicity, and perpetuation of cultural features of these bacilli justify the placing of them in a separate group.

I. Primary Carcinoma of the Appendix Vermiformis. II. Carcinoma of the Appendix Secondary to Carcinoma of the Ovaries.—Elizabeth Hurdon describes two cases. The diagnosis of this affection is, of course, extremely difficult, owing to the absence of distinctive symptoms in the early stages. Our attention is first directed to the iliac region by the onset of pain and the presence of tumefaction, and when these are manifest the growth is usually well advanced. There is ordinarily no interference with the digestive function until the growth has invaded the cæcum or the large or small intestine. The diseases for which carcinomatous appendix is most apt to be mistaken are: cyst of the appendix, calculi, tuberculosis of the so-called neoplastic form, impacted fæces in the cæcum or small intestine. In many instances only an exploratory section will enable one to make a positive diagnosis. If the appendix is found to be the seat of a new growth, in order to secure its complete removal the head of the colon should be resected, and should the growth have visibly extended beyond the appendix a more extensive resection may be indicated.

A Case of Transient Spastic Convergent Strabismus.—Samuel Theobald reports a case, due in all probability to an irritation of influenzal origin of the innervation centre which controls the associated action of the internal recti muscles. It disappeared under the influence of atropine, a normal muscle balance being re-established in a few days.

Charles Frederick Wiesenthal, Medicinæ Practicus, the Father of the Medical Profession of Baltimore.—By Eugene F. Cordell.

On the Present Status of Therapy and its Future.—By Lewellys F. Barker.

The Edinburgh Medical Journal, August, 1900.

The Feeding of Phthisical Patients in Relation to the Wasting of the Body.—Vincent Dormer Harris says that the object we should aim at is not to increase the weight of the patient by a mere deposition of fat, but rather to set up a more healthy metabolism in the tissues, and especially in the muscles, in which so much of the active metabolism takes place. With this object in view, it would seem to be unwise to increase any one of the three varieties of food stuff to any large extent, at the expense of the others, but if any is to be increased it should be the proteid. Food should be given in the most appetizing form possible, well cooked, and in variety. Preserves, honey, and marmalade with breakfast are good, and relishes frequently stimulate the appetite. Fat may be given as cream, fresh or clotted, bone marrow, yolk of eggs in wine, caviar, fish roes, etc. Frequent small meals often help to overcome anorexia. The author has little confidence in increase of weight exhibited by patients who are lying down and inactive most of the day, but progressive increase in weight, maintained while the daily amount of exercise is gradually increased, appears to be of real value as an indication of improved tissue metabolism.

Suppression of Urine Following Cystitis.—J. Lamond Lackie reports a case of chronic cystitis; there was double infection of the kidneys, but, strange to say, there were no symptoms pointing to renal affection until a short time before death, when complete suppression of urine occurred, and even then the patient did not feel especially ill until complete anuria had existed for ten days. After that occurrence, there was a continuous flow for eight days, and again for four days before death no renal secretion occurred.

The Treatment of Simple Goitre in Young Adults.—George R. Murray calls attention to the satisfactory results obtained by the treatment of some forms of enlargement of the thyroid gland by thyroid extract. Exophthalmic goitre must be excluded, for its symptoms are often aggravated by this treatment. Liquid thyroid extract or dry thyroid may be given; the author uses the officinal preparations, giving of the former ♏ xv. twice or thrice a day, and of the latter gr. iii. or more two or three times a day. He reports three cases which illustrate his point.

The Action of the Heart in Mitral Stenosis.—C. C. Gibbes discusses the various theories held in regard to the mechanism of this disease, and says in conclusion that he considers the predominant feature of mitral stenosis to be a want of synchronism in the action of the two ventricles, the right assuming in part the function as well as the rhythm of the left auricle.

Points of Practical Interest in Surgical Gynæcology. IV.—Conservatism and its Influence on Operative Technique.—By H. Macnaughton Jones.

Uretero-Vaginal Fistula, with Notes of a Case for which Uretero-Cystostomy was Performed.—By E. Arthur Gibson.

Remarks on the Treatment of Dacryocystitis and Lacrymal Obstruction.—By W. Ernest Thomson.

Dublin Medical Journal, August, 1900.

Pemphigus with Erythema Circinatum.—H. C. Drury reports the case of a boy aged fourteen years, with a scanty eruption on the face, chest, and arms, consisting of groups of small vesicles for the most part the size of boiled sago grains, some few being the size of small peas; there were a few on the eyelids and cheeks, also a few scattered about the chest and arms. In the course of twenty-four hours he developed a most extensive gyrate or circinate erythema over the entire trunk and upper parts of arms and legs. This consisted of larger and smaller circles, sharply marked off from the healthy skin by a distinctly raised margin. These circles were of a bright red color, somewhat paler in the centre than at the margins; some were separate, but many coalesced, forming large, irregular gyrate patches. The vesicles seen on the previous day, though still for the most part small, were a little larger than before. On the next day the erythema had faded, though the evidences of it had not disappeared. The whole body was mapped out by gyrate markings; the margin still could be felt by the finger to be distinctly raised; inside this the patch showed a very faint brownish discoloration, which when viewed from a distance was distinctly seen, but when looked at closely could hardly be said to be different from the healthy skin outside the bounding ridge. In addition to this, however, a great increase had occurred in the size and number of the vesicles and bullæ. For six or seven days after admission the bullæ increased in number and size, this latter feature being due partly to increase in individual bullæ, but chiefly to the coalescing of several, so that huge, irregular bags of fluid were formed, measuring in some cases as much as three inches by two inches. The patient did well on arsenic, and was discharged on the twenty-first day of treatment in good condition, though not entirely well.

Remarks on Dupuytren's Contraction of the Palmar Fascia.—J. Knott saw five cases in old soldiers whom he examined for pensions. Two of them had the lesions of chronic rheumatic arthritis. In all the contraction engaged the ring finger of the right hand and passed to the little finger of the same side. The corresponding fingers of the left hand had afterward become affected, but always to a slighter degree. Several other cases are also alluded to. Knott gives a history of the literature of this affection, and makes an interesting digression concerning the place of the ring finger in classical studies on the hand. In every instance he has examined he has found some evidence of the coexistence of what he calls the fibroid diathesis. He believes that the skin is involved as well as the deeper structures. The relationship of the palmar fascia to the overlying skin also contributes to give to this condition some of its peculiar features. Anatomists are familiar with the fact that the separation of the skin from the subjacent "deep fascia" presents special difficulty in the case of the palm of the hand and sole of the foot, as also in the case of the scalp. The skin in these localities is, so to speak, nailed down to the strong fascia beneath by vertical pegs of dense fibrous tissue. This arrangement accounts for the fact that the skin cannot be pinched up in these places; also that the subcutaneous tissue does not become the seat of fatty deposit or of œdematous infiltration to any marked extent. The cirrhotic process had had the effect of approximating the surfaces of skin and fascia, and the amount of "granular" fat normally found in this situation was reduced to a vanishing quantity. The ring finger is especially involved because it is a place of least resistance, owing to the peculiar arrangement of its tendons.

The Nose, Cold Feet, "Tobacco" Heart, and Convallaria Majalis.—H. S. Purdon ascribes the cold feet and redness of the nose often seen in smokers to the weakened action of the heart from tobacco poisoning. He advises convallaria internally, while suggesting calisthenic exercises with the arms, bending the body, and pressure with the hands "off and on," over the epigastric region, which help to restore "tone" to the heart. For the cold feet and in all cases of any redness of the nose, especially in those of the female sex, no matter how caused, a mustard foot-bath at night for ten or fifteen minutes, followed by brisk friction, and in winter a "hot-water bottle" in bed, is most useful as well as comforting. For the local treatment of redness of nose, a sulphur and calamine lotion rubbed into that organ stimulates the skin circulation and does good in restoring a natural appearance to that prominent and important organ.

University Medical Magazine, August, 1900.

Perichondritis of the Larynx in Typhoid Fever.—M. Howard Fussell reports two cases, both occurring during convalescence from typhoid, which had been mild in one case, severe in the other. In both the laryngeal symptoms appeared after some sort of exertion of traumatism, in the one swallowing an apple, in the other the shock of opening a rather large abscess. In both the severe symptoms came on suddenly and threatened life in a very few hours. In both cases there was early some slight disturbance of breathing, in one some hoarseness. Operation was refused in the case of the patient who swallowed a large piece of apple, although he was suffering tortures from stenosis. He died in three days. The post-mortem showed a huge abscess of the cricoid cartilage. The second patient recovered after tracheotomy. He wore the tube constantly for six months. The patient remains well, with a slight stridor in breathing, and hoarseness of the voice and some dyspnœa on exertion.

A Case of Migraine with Aphasia and Numbness in One Arm.—Samuel McC. Haniell reports the case of a young man aged twenty years, who at seventeen years, while preparing for the final examination of his college year, began to suffer from hemicrania. At the beginning of the attacks there was visual disturbance, with a peculiar sensation in the epigastric region, relieved by loosening his clothing, then numbness with loss of sensation, first in the little finger, then the fingers in succession and the thumb, the hand, and the forearm to the elbow. Following this there was numbness in the lip and one side of the nose, and on several occasions he had difficulty in speech. The head pain began very shortly after these phenomena, gradually augmented, became very severe, and subsided in from three to five hours. There was never any suggestion of a convulsive seizure. The author protests against the view held by many at the present time, that migraine is closely allied to epilepsy.

Malignant Precocious Syphilis.—H. M. Christian has seen eight cases during the past two years. In all of them the precocious type of the disease was shown by the early appearance of ulcerative and pustulo-crustaceous lesions, most particularly marked upon the lower limb. Apart from the varying forms of cutaneous lesions presented by these patients, the following conditions were found common to all: progressive loss of flesh, anæmia—the result of a marked leucocytosis—hectic fever, insomnia, and night sweats. In the treatment of these cases, no time should be lost in giving mercury by the mouth, or by daily inunctions, the latter being the more suitable method of employing the remedy. Iodide of potassium should be given in ten-grain doses three or four times daily. Tonic and stimulating methods should be employed, such as are resorted to in the treatment of any wasting disease.

A Case of Pneumonomycosis due to the Aspergillus Fumigatus.—By Leonard Pearson and Mazyck Ravenel.

Some Personal Observations on the Plague.—By H. M. Miller.

Revue de Médecine, August 10, 1900.

Diseases of the Spinal Cord in New-Born and Nursing Infants with Hereditary Syphilis.—De Peters gives a detailed study of eleven cases, in which various forms of paralysis testified to affection of the spinal cord. In nine cases there was the "*Flossenstellung*," outward deviation of the wrists; in two paralysis of the nucha and upper extremities, and in nine paralysis of the upper extremities without affection of the nucha. The author gives his reasons for attributing the paralyses to hereditary syphilis. Treatment consisted in friction with gray ointment, the internal use of calomel, and the administration of potassium iodide to the mother, and was followed by surprisingly rapid and good results.

Acute Dysenteric Hepatitis.—Paul Remlinger concludes a study of four cases of this affection as follows: Dysentery is capable of occasioning either acute hepatitis or liver abscess. The diagnosis between these two affections is possible, but difficult. Exploratory puncture will solve doubt and will precede operation in the case of abscess, and bleeding of the liver in the case of hepatitis. Whether this bleeding acts simply by relieving congestion, or by withdrawing a certain number of micro-organisms and favoring leucocytosis, it is followed by rapid improvement of the local and general conditions, and a recovery so complete that no other form of treatment can bear comparison with it.

Simple Persistence of the Arterial Canal.—By G. Gérard. A continued article.

Sadism at Bullfights.—By Charles Féré.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

WEATHER CHANGES—ECHOES FROM IPSWICH.

LONDON, August 17, 1900.

WE are still awaiting the arrival of your heat-wave. Some of the weather-wise say it has been turned aside by the east wind from Spain; others think it has only been tempered thereby. At any rate we have had a week of delightful warm summer weather. Yesterday twelve hours of sunshine at a bearable temperature has made us forget the wet holiday week, and to-day is nearly as fine, though a thunderstorm seems to be brewing.

The scandal of the National Hospital for Paralysis and Epilepsy advanced a stage on Saturday, when at least sixteen governors seem to have attended the meeting; for a resolution of the board was carried by fourteen votes to two, that "it is inexpedient to grant the demand of the staff for direct representation on the board." What next? I have just received from my college a note saying that on the 26th ult. it was resolved to circulate again a resolution passed on the 25th of October, 1888, in the following terms: "That it is undesirable that any fellow or member of the college should be officially connected with any company having for its object the treatment of disease for profit." It seems to me difficult to imagine a more feeble action on the part of so influential a college. I am half inclined to think it an impertinence to warn me against such an "undesirable" proceeding; but then I remember there are some fellows who have been guilty.

The little "odds and ends" gathered from conversations about the doings at Ipswich are sometimes interesting and often reflect floating opinions which may not find other expression. There is certainly widespread indignation at the amazing effrontery of the Council in endeavoring to seize all the authority and the accumulated funds of the association. On the other hand, there is, perhaps, an equally widespread indifference as to what the wire-pullers may do, mingled with mild contempt for everything pertaining to the association, except in relation to any sign of scientific progress.

A curious circumstance connected with sectional management may be noticed. In some sections the president announced that he had been requested not to deliver a formal address, and called upon the openers of the discussions to proceed with their papers; in other sections the old formality of a presidential address was observed without remark; so there are conjectures as to whether the request was general or partial, and inquiries as to by whose authority the requests were made. Certainly the profession has lately had a surfeit of addresses, and the time of the sections is often insufficient for adequate discussion, while sketches of what has been done are of little interest to audiences supposed to be devoted to the departments under review. These sectional formalities must be distinguished from the three addresses before the whole association, which are on a different level. I gave you a note or two on that in medicine. Dr. Smyly's address in obstetrics should interest every general practitioner. It might well be summed up in the old adage against "meddlesome midwifery," only the aphorism was thoroughly applied as to every up-to-date measure.

In the Psychological Section, Dr. R. P. Smith gave an address in which, admitting the increase of insanity as to which so much has been said, he boldly urged the necessity of attacking it at its sources. These are heredity, alcoholism, and syphilis. Legislation is not likely to forbid "free trade in marriage." Probably persons who have even suffered attacks of insanity, will, in spite of the risk, continue to marry. Many have done so with disastrous results. Others who have not actually suffered attacks are liable

through heredity. Then there are the cases of break-down after marriage. Further, it is a sad fact that congenital imbeciles and chronic epileptics have added many bad specimens to the stock. Should they be prevented from marrying? Dr. Smith would say yes, but how to do it is not an easy problem. The second most powerful cause of insanity is alcoholism, and surely it would be easier to deal with this than with the first, but though the subject is ever before Parliament no really practical measure has been passed restricting the influence of this poison. So we go on building new asylums at enormous cost for preventable diseases, and no doubt shall do so until the oppressed rate-payer, on whom are heaped the costs, rises in his might and insists on a change. The third source of the evil—syphilis—is now seen to be more active than was supposed, and it is unquestionably more difficult to restrict it. Notification is the popular panacea with many, but I doubt its applicability here. Dr. Smith is doubtful if the ensuing century will be marked by an arrest of insauity in these sources, but he thinks that is the direction in which our efforts should tend.

In the Section of Diseases of Children, Mr. Muirhead Little read a paper dealing with one hundred and fifteen cases of infantile paralysis. He gave full details of the deformities met with and the muscles that suffered. These statistics brought out the fact that has been before noted, that the left lower limb is more often attacked than the right and that the tibiales anticus and posticus were far more often palsied than any other muscles, and the quadriceps extensor was affected twice as often as the hamstrings. He gave details of eight cases in which tenoplasty was performed, and of four in which he had stiffened the ankle. He remarked on the difficulty of deciding how much of the resulting benefit was due to the removal of the deforming muscle and how much to the newly constituted muscle. In the discussion which followed speakers had nothing to say on the statistical part of the paper, but confined themselves to discussing the operations. The general feeling was distinctly in favor of tenoplasty, and especially of Nicoladoni's operation.

As we are engaged in war, and much heart-searching as to our preparations for it, the new Section on Army, Navy, and Ambulance naturally attracted attention. The past, present, and future of the Royal Army Medical Corps was discussed. So was the volunteer medical organization. The necessity of increasing both is becoming a conviction on the part of the public. A motion was carried by Surgeon-Captain Cantlie, asking the Council to appoint a committee to draw up a scheme to submit to the government for reorganizing the medical services of the auxiliary forces on the basis of the system of the Royal Army Medical Corps, and bringing into unison the medical services of the regular and auxiliary forces.

Your reporters have no doubt told what took place about the journal of the association. Some talk of Mr. V. Horsley's "attack on the editor" as if it were a personal affair, but he disclaimed any such intention. Others say it was time some one spoke out, and it was well that a strong man undertook the task. The positiou of the editor is no easy one, with the Council and journal committee and members to cater for. You will no doubt sympathize with him, as I do, for an editor in harness and driven by conflicting influences may well stumble. But Dr. Dawson Williams has really raised the tone of the journal since he took the reins. Any blame about the articles concerning the Exeter Hall attempt should be put on the shoulders of the wire-pullers, who seem to have concealed from the editor their full intentions, just as they must have done from Dr. Ward Cousins, for he is not the man to have willingly cajoled his hearers. If you read between the lines of Mr. Horsley's speech, which has been published in full in the journal, you will see that he did not really attack the editor personally, but only hit out at the others through the official, and the editor's defence was satisfactory so far as he was himself concerned.

THE PLAGUE IN BEYROUT.

(From our Special Correspondent.)

Beyrout, July 21, 1900.

They have left the city and gone to the mountains this time with a vengeance; not because the summer is upon us in full force, but for another reason, to wit, the "plague" was "declared" about fifteen days ago—on Friday, the 6th of this month. It came about in this way: Three men and a boy aged fourteen years, who used to work in a pit, a cellar, or a charnel-house, whichever you like to call it—their occupation being the making of sweetmeats, no less, for the multitude—fell ill suddenly. They came out of their residence and had a promiscuous and heavy meal, composed of I don't know what, but I have been informed that the symposium was a mixture in one course of sweets (of course), vegetables, cheese, melon, raw cucumbers, and some dishes the composition of which is a mystery, filling up the details with bread and onions raw. They had been fasting, no doubt, these three men and a boy, and being a-hungered ate heartily. Then the end came. All three were stricken down with vomiting and diarrhœa and collapse.

The quarantine officer, or the port medical officer of health, was sent for and "declared" the malady to be "plague." Other medical men were sent to consult with him, and the case hung fire, the consulting physicians being opposed to the diagnosis (quick as it was) of the sanitary officer. He held his ground, however, and on Saturday evening, the 7th of July, the declaration of plague was confirmed in Beyrout. Then came the stampede. The plague was a subject of further investigation. A rabbit was inoculated with the blood of one of the victims. It fell sick unto death. All in Beyrout were hanging, so to speak, on the life of the little rodent, and when it died, seventy hours after the inoculation, there was a panic. Twenty-five thousand inhabitants left the town in one day. The road for twenty-one kilometres (fourteen English miles) was one line of carriages, outriders, muleteers, camels, baggage carts, and mules in abundance laden with household property, donkeys ditto, men, women, and children on foot tramping up, all (except the beasts of burden) terror-stricken, to the shelter of the hills. Not knowing the circumstances, one could not well have said whether it was a grand funeral procession or an invading army.

Then the amusing part comes in. As I said, "la Peste" was confirmed on Saturday evening, the 7th inst. Now all the merchants here send their families to "the mountains," going to visit them from Saturday till Monday, returning on that day by the early train to look after their various businesses, from the banker to the man who sells you a yard of tape. All these went off in the best of health and in the enjoyment of good spirits on that fatal Saturday afternoon—to come back no more. On the night or evening of that fated or fatal Saturday all communication by rail or road was cut off—no one and nothing was allowed to cross the frontier to the highlands, so that the train our friends were waiting and waiting for never came. It was lying snugly without a sign of life in Beyrout station. It used to be full of energy early of a morning, puffing its little soul out to be in readiness to fetch the swarms of folks from Aleigh to the capital. But now not a puff, not a running to and fro—even the throttle valve was silent; and it lay, did the little engine, stiff and stark in its engine-shed. The news of the plague surely could not have succeeded in putting out its fires and extinguishing its lights, while all the multitude waited and wept for it in breezy Aleigh with its dust by day and its fogs by night.

On the top of this came the "cordon" (of course Beyrout had already been put under quarantine to outside ports and the yellow flag hoisted), by which we mean an encircling line of armed dragoons surrounding and cutting off the town and suburbs of Beyrout from any communication with the hills of Lebanon. Did it end there? By no means. We were not allowed to go to Lebanon, and Lebanon was not allowed to come to us! As the merchants could not come down, all their stores, shops, and warehouses are closed, or most of them, and only that we are not enlivened by an occasional shell from above, and in that we have the sea open to us, upon our word it looks like another Ladysmith. No vegetables in the market, very good mutton, and very bad beef. Thank goodness we are few, so the supply of the latter is good and the price has gone up very little. Flour has gone up, however, 17.5 per cent., which is a very bad thing for the poor in our midst, bread and herbs being their sheet-anchor to save them from starvation. The principal streets are being repaired and macadamized at a furious pace—the deus and purlieus of the inner circle of the bazaars are more unkempt and filthier than heretofore.

Should this plague scare turn out a fiasco, as I think it will, there "will be trouble in the town." Somebody—I think it was a Jesuit father—claims to have discovered the real true and undeniable bacillus of "la peste." "It is not," I am informed he says, "the absolute bacillus, but that of the third degree." Well, what could he have more? All this on account of four men and a boy aged fourteen who shut themselves up without sunlight—the only sun was their candle or lamp—and of fresh air there was none, coming out of their burrow and filling themselves to repletion at a temperature of about 90 F. in the shade. Business is stagnant, merchants will lose a vast amount of money, the ships refuse to land or take cargo, we are a beleaguered city—and all on account of four men and a little boy of fourteen, who are doing merrily and well after their fifteen or sixteen days' experience of the "Forest"—a grove of stately pine-trees outside the city wall.

No case has been "reported" since, and the health of the town, considering the season, is practically good.

Surgical Suggestions.

Varicose Veins.—

℞ Barii chloridi..... 2
Aquæ destil .....q.s. ut ft. sol.
Lanolini 60
Ol. amygdalæ dulc..... 1
M. S. Use three times daily with friction, where blue veins shine through the skin.

—Alex. Rixa.

Pruritus Ani.—

℞ Fluid extract of hamamelis..... 1
Fluid extract of ergot 2
Fluid extract of hydrastis..... 2
Compound tincture of benzoin..... 2
Carbolized olive or linseed oil (5 per cent.) 1
M. S. Shake well and inject from one to three drachms daily

Paint with a solution of silver nitrate, using a two-per-cent. cocaine solution to prevent excessive pain. After two or three burnings, apply citrine ointment, cover with cotton, and secure with T-bandage.—Adloe.

Bites of Fleas, Mosquitos, Gnats, etc.—

℞ Ol. chamomillæ camphorat..... 100 parts.
Liq. styracis..... 20 "
Spt. menth. pip..... 5 "
M. S. Apply.

—Brocq and Jacquet.

Hemorrhoids.—

℞ Carbolic acid, saturated solution..... ʒ i.
Ol. olivæ..... ʒ ij
M. S. Inject five or ten drops into each tumor, injecting as the needle is withdrawn.

Reinsert into any part that does not turn white. Treat all tumors at one sitting. Smear with vaseline, press well inside, and put patient to bed.—Monroe.

Paraldehyde and Chloroform given together do away with the period of excitement and cause anæsthesia more rapidly and with less chloroform than when the latter is used alone.—Cosimo Noto.

Closed Inhalers are cumbersome, unclean, unscientific, and dangerous. The best inhaler is the simplest; one made with a towel or an "Allis" for ether, and a folded towel for chloroform.—H. A. Hare.

Nævi, Lupus, and Scar Tumors may be treated with advantage by the elastic bandage. The good results are due to pressure, warmth, and moisture, and protection from external irritation. The band may be removed every day so that it, as well as the skin, can be thoroughly cleansed.—Serenin.

Lupus.—Calomel may be injected or Robins' pills given:

℞ Hydrarg. chl. corros.,
Sodii chloridi,
Vin. thebaic.....āā 1
Mic. panis..... 5
Gluten..... 2.5
Glycerin..... 2–3
M. ft. pil. No. c. S. One to three daily with meals.

Bleeding from the surface of an internal organ or from a single vessel may be checked by directing against the seat of hemorrhage a current of hot air (39° at 5 mm.) from the Holländer apparatus.—*La Semaine Médicale.*

Nasal Stenosis from Defective Septa.—Briefly this operation consists of four steps: 1. Buttonhole the septum at the point of greatest obstruction, and incise obstructing ridges or convexities in the line of convexity. 2. Break with forceps all fibrous bands and separate the cartilage from the superior maxillary spine at the floor of the nose. 3. Overlap cut edges and introduce splints. 4. Treat antiseptically for two weeks. It restores the entire septum to its normal position, corrects slight external deformities, and leaves both surfaces of the septum parallel. It is adaptable to all forms of deformities or deflections. No perforations result, no granulation tissue is left behind, and better and more uniform results have been obtained by me than by other methods.—Beaman Douglass, in the *Laryngscope*, June, 1899.

Strabismus should be treated early with glasses and parents be made aware of the following dangers of neglect in this particular: Permanent cross-eyes, partial blindness; necessity of operation in after years which will straighten the eyes but will not cure the blindness.

In Resection of the Gasserian ganglion the sphenoidal sinus should be guarded against injury and infection which might have fatal results. There is less danger by the Krause-Hartley than by the pterygo-maxillary route.—O. Jacob.

In Heat-stroke with convulsions and œdema of the lungs, the patient was benefited by venesection.—C. Klein.

Fracture of the Nose in its Upper Portion.—Waste no time in an attempt to replace the bones from the inside nor in applying plasters, etc., externally, but make a median incision and replace the fragments, holding them in place with fine stitches.—Büdinger.

To Preserve Rubber Articles keep them in a one-per-cent. solution of formol or zinc chloride, or a concentrated solution of boric acid. They should never be left exposed to the air or to the action of cold.—Krolikovski.

Linen is entirely unsuited for the proper application of ointments to the skin, and still it is popularly thought essential.

Late Union is more apt to occur in fractures of the upper third of the humerus than elsewhere; a prognostic point to bear in mind.

Iodoform Odor may be removed from the hands by thorough washing in vinegar after the use of soap and water.

Extemporized Dressings.—Cheesecloth cut into strips or squares is rendered alkaline by boiling for twenty minutes in a solution of washing soda (two ounces to a quart), then wrung out and boiled again in clear water, previously boiled and allowed to settle. It is then passed through a bichloride solution (1 : 200) and packed moist in jars previously sterilized or washed in bichloride solution (1 : 200). Just before using it is wrung out in bichloride solution (1 : 2,000). —*The Clinical Review.*

Note on a Case of Webbed Penis.—L. Grounauer mentions a case of deformity of the penis in a child aged seven years, submitted to operation, and calls attention to the extreme rarity of the condition. The penis portion was attached to the scrotum, drawn up and separated from the pubic region by a marked furrow which dipped down upon either side in the arc of a circle to near the frænum, and showing externally the separation between the penis and scrotum. The penis was drawn down so that the meatus looked downward by the combined adhesion to the scrotum and a marked shortening of the penile portion of the urethra. An operation separated the parts successfully and restored the penis to approximately normal conditions. —*Revue Médicale de la Suisse Romande*, July 20, 1900.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-eighth Annual Meeting, Held at Ipswich, July 31, and August 1, 2, and 3, 1900.

(Special Report for the MEDICAL RECORD.)

SECTION OF GENERAL MEDICINE.

(*Concluded from page 310.*)

Second Day—Thursday, August 2d.

The Problem of Gastric Ulcer.—This discussion was opened by DR. J. F. PAYNE, of London, who said he would present several problems, discussion upon which he trusted would prove of interest. He first took the prevalence and mortality of gastric ulcer and showed from statistics of upward of six hundred cases spread over a period of thirty years that the disease was apparently increasing both in prevalence and mortality. He could find no satisfactory explanation for this, but thought it was suggestive that the same held true for other abdominal diseases. He had looked up the records of appendicitis for twenty years, and there seemed to be an enormous increase in this disease, which he put down to better methods of diagnosis. He said that cancer of the digestive organs had increased more than cancer of other organs, and typhoid more than other zymotic diseases. He was not prepared with an explanation. The next question he brought forward was that of diagnosis, and he asked whether all cases so diagnosed were really gastric ulcers. He reviewed in detail some of the main symptoms, and pointed out that the principles of diagnosis were with one exception the same thirty years ago as now. The only new symptom of importance was that of hyperacidity of the gastric fluid, of which he would speak later on. With regard to the typical pain in the stomach after food, circumscribed, often severe, and associated with circumscribed tenderness, he had found that it was absent in the majority of his cases. Vomiting was recorded in more than half. He was surprised to find that hemorrhage was often absent in fatal cases, whereas it nearly always took place in the non-fatal. He supposed that the rapidity of a fatal termination by perforation was the explanation. This raised the question of correctness of diagnosis. Hæmatemesis was fatal apart from gastric ulcer. He had collected one hundred and four cases, and he had found that chronic alcoholism and cirrhosis of the liver were the most common causes in males. Aneurism was rare. He believed that a strain might be the starting-point of a gastric ulcer, and he instanced several cases. He came to the conclusion that hemorrhage from the stomach in grown men was most commonly due to alcoholism, but that in the young and in women gastric ulcer was the most frequent cause. He now referred to the symptom of hyperacidity of the gastric fluid, to which attention had been drawn by German writers. They nearly always detected hydrochloric acid in excess, and considered it of such value that they washed out the stomach in all suspected cases. They believed this hyperacidity a cause of gastric ulcer. Others, on the other hand, had not found it, but it became a question how far it was allowable to wash out the stomach. The next problem was, could a distinction be made between acute and chronic ulcers, and he believed that only in fatal cases which were brought to the post-mortem table could we distinguish for certain. In forty-eight fatal cases the symptoms in thirty-six had lasted over one month and the appearances were those of chronic ulcer; in twelve the appearances were of acute ulcer and the symptoms had lasted less than one month. He found of non-fatal cases that in thirty-four per cent. the symptoms had lasted one month or less, and in sixty-six per cent. they had been present for more than one month. Among the former were only twice as many females as males, while the females in the latter were four and one-half times in excess of the males. He knew these figures did not accord with Dr. William Fenwick's. He asked of if there was any criterion of acute disease, or whether a chronic ulcer was anything more than an acute ulcer grown older. Coming to the problem of etiology he considered that of the many factors which had been brought forward as possible causes of gastric ulcer he believed the theory of auto-digestion offered perhaps the best explanation. It would at all events account for the persistence and chronicity of the disease. The precedent conditions were, however, still unexplained, and he did not think that bacteriology helped us very much at present. As regarded sex, his tables showed that, of those who died, the sexes participated nearly equally, and he was able to point out that, although the disease was commoner in women, it was relatively much more fatal in men. The male mortality took place principally in the later periods of life, the female in those under thirty years. The proportional mortality for all cases in later life was high. It had been said that the disease was most common in young women of the poorer classes. Considering the enormous numerical preponderance of the poor, he doubted if this were true. As to prognosis he had little to say at that time, but he believed that, speaking briefly, in the young it was good, in the elderly bad. On the subject of morbid anatomy he would only say that he did not take the occluded vessels with coagulation of their contents—a condition not infrequently found—as evidence of thrombosis. He strongly advocated treating the disease by rectal injections. He admitted that that was a process of slow starvation, but pointed out that by allowing the patient to drink small quantities of water this method could be employed for two weeks or more. He deprecated the employment of lumps of ice. He remarked that acetonuria had been observed in rectal-fed patients. Acetone in the urine was decidedly common in other conditions than diabetes, especially in alcoholic dyspepsia, and he regarded it as due to starvation.

DR. HABERSHON, of London, displayed some interesting tables drawn up from his late father's private notebook. They supported much that Dr. Payne had said, and went to show that gastric ulcer was not uncommon in young women of the upper classes. He thought that there must be some very potent cause for the prevalence of this disease in young women. There were, he maintained, three classes of cases in which the diagnosis was often extremely difficult. They were, first, those occurring in young women with no history of hæmatemesis; secondly, the neurotic class, in which there was extreme hyperæsthesia often located in such situations as gave rise to grave suspicion of gastric ulcer. In this connection he related what had been handed on to him as a "tip" in dealing with this class, and which he had found to be of the greatest possible practical assistance, namely, that while pressure was made over the epigastrium with one hand, firm pressure should be made upon one of the carotids with the other. He found in this way that the imaginary pain fled in a remarkable manner. He was unable to say how this came about, but he suggested that it acted either by cutting off some of the circulation through the brain or by direct pressure upon the pneumogastric nerve. The third class, which he found difficult to diagnose, were those in which the pain was relieved by food. It was in these that the ulcer was found near the pylorus.

Dr. W. Gordon, of Exeter, reviewed the many well-known theories as to the etiology of the disease, but he did not attach value to any. He set aside the idea of either thrombosis, embolism, or simple submucous hemorrhages with subsequent auto-digestion, and regarded such causes as trophic lesions, scalding food, tight lacing, or wounds as most unlikely. He believed the explanation would be found in some organism associated with alkaline reaction of the gastric fluid. On this account he very strongly advocated the systematic bacteriological examination of all excised ulcers. Eight or nine years ago he had an opportunity of examining a very typical example of acute perforating gastric ulcer. The specimen, which had been some time in spirit, showed a clean circular hole punched out as it were in the stomach wall, with no evidence of induration or even swelling around it. Sections into the surrounding tissue starting from the edges of the ulcer were made, and stained with methylene blue showed what was at least suggestive. The edge of the ulcer was confused and almost structureless, having apparently undergone digestion. A little way from the edge there was indication of a certain amount of inflammation with aggregation of leucocytes, and (what impressed him most at the time) beyond the leucocytosis and reaching for some distance into the stomach wall were numerous cells stuffed with micrococci, and free groups of micrococci were scattered in the tissue. On the free edge of the ulcer there were also microbes, but they were various, both bacilli and cocci. He had not pursued the investigation at the time, for it seemed to him that without fresh specimens, *i.e.*, specimens excised in life, no useful result could be arrived at, and eight years ago excision of the ulcer was not even spoken of. Now in certain cases the material had become available, although he himself had had no opportunity of making use of it.

Dr. Calwell, of Belfast, addressed himself to the question of whether it were not possible to prevent adhesions forming from gastric ulcer. He strongly urged the importance of treating even slight cases of acute dyspepsia with this end in view. His practice was to advise bed and complete rest for days, and he did this because it was his belief that many patients suffering from acute dyspepsia had as a matter of fact small gastric ulcers. He said the presence of adhesions had been denied, but he had evidence of strong adhesions in sixteen cases upon which he had operated. One of these patients had had an attack of epigastric pain on making a sudden movement. He related a case of acute hemorrhagic pancreatitis in which he had found adhesions to the pancreas.

Dr. Julia Cock, of London, related two very interesting cases which pointed to difficulty in diagnosis. In both, the symptoms simulated gastric ulcer. The first was that of a young girl with all the symptoms of gastric ulcer, including hæmatemesis, which was severe and for which she was admitted to hospital. She was under observation for some weeks, her symptoms being always such as to suggest gastric ulcer. The question of laparotomy was raised. At the post-mortem there was subphrenic abscess with pleurisy and pneumonia from extension, while there was absolutely no explanation for the hemorrhage. Miss Cock thought that in young women hæmatemesis without ulcer was more common than was supposed. The second patient was an older woman, and her symptoms spread over a period of eight years. At first she presented the typical symptoms of gastric ulcer, having several attacks of pain and hæmatemesis; she was also phthisical. A laparotomy was performed for symptoms of perforation and the stomach was found healthy. An interval elapsed which was followed by recurrence of the pain which now became constant. A second laparotomy was done and chronic adhesions were found and divided. The stomach was perfectly healthy.

Dr. Newton Pitt, of London, had long held the view that hæmatemesis in young women was not necessarily due to gastric ulcer. He had been struck by the wide divergence between the clinical and the post-mortem evidence. He himself had made two autopsies on patients with hæmatemesis and had found no cause for the hemorrhage. He related a similar case to Miss Cock's, and suggested that hæmatemesis should be the diagnosis until there was positive evidence of gastric ulcer. On the other hand, hemorrrhage, as shown by Dr. Payne, was often absent in fatal cases.

Mr. W. Stuart Low, of Kirkbank, after some remarks on the anatomical relations of the stomach, said that he had had very good results from the use of mucin, which he tried in ten cases of acute dyspepsia, the pain and constipation being speedily relieved. He considered this to be a logical method of treatment when the position of the mucous secreting glands of the stomach was remembered. They were nearest the surface and suffered most. He dieted his patients carefully, but objected to peptonized foods and rectal feeding.

Dr. Pye-Smith, of London, remarked on the difference between the clinical and the post-mortem evidence in respect to the age and sex incidence of the disease under discussion. He had collected cases which entirely bore out what Dr. Payne's tables showed. He was much interested in Dr. Gordon's suggestion as to the pathology, and agreed that a bacteriological investigation of the freshly excised ulcer was likely to help us to an explanation of the exciting cause. He considered that it was important to bear in mind the different appearances that an acute perforating ulcer and a chronic funnel-shaped ulcer presented. He was familiar with these cases of hæmatemesis occurring in young women without any apparent cause, and likened them to the nose-bleedings from which boys so often suffered. He regarded hæmatemesis without ulcer as an epistaxis of the stomach, so to speak. He took a favorable view of the prognosis in cases of hæmatemesis. He believed that it might be said with truth that hæmaturia was never fatal, hæmatemesis from gastric ulcer very rarely, and hæmoptysis only occasionally. He advocated treatment by rectal feeding, and agreed that small draughts of water, and especially warm water, not only were harmless, but he believed they were of distinct advantage.

Dr. Saundby, of Birmingham, said he was quite at one with those who laid stress on the difficulty of diagnosing gastric ulcer. He had always been in the habit of pointing this out; but at the same time he would not go so far as Dr. Pitt, for in that case it came to never diagnosing the disease at all during life. His practice was to speak of anæmic gastralgia until hemorrhage occurred, when he thought it was safe to diagnose gastric ulcer. He was inclined to be sceptical about the value of the statistics which had been brought forward, for he could not, from his experience, agree that gastric ulcer was more fatal in elderly people. He was sure that hæmatemesis from gastric ulcer was very rarely fatal. In a long experience at the Birmingham General Hospital he had had only one fatal case. His routine treatment consisted of rectal feeding for twenty-four to forty-eight hours; he then gave milk and lime-water in gradually increasing quantities. He usually prescribed a mixture containing the sulphates of magnesium and iron, advising his patients to continue this for a considerable period.

Dr. Pope, of Leicester, said that no mention of drugs had been made throughout the discussion except by the last speaker. He himself was in the habit of giving his patients resorcin in doses of gr. v.

He believed the pain and discomfort were materially relieved by this method of treatment.

Dr. Payne, in his reply, said he was somewhat disappointed that the problem of prevalence had not been touched upon by any of the speakers. He was interested to hear Dr. Gordon's remarks, and was inclined to believe in the theory of the bacterial origin of the disease. In support of this opinion, he had seen in one autopsy two ulcers occupying such positions that when the walls of the stomach came in contact the ulcers closely approximated in a way that he thought was suggestive.

Intermittent Pulse.—Dr. Arthur R. Cushny, of Ann Arbor, Mich., read a paper on this subject. He differentiated four types of irregularity, ascribing them to excessive or deficient contraction of auricles or ventricles.

Third Day—Friday, August 3d.

Explanation of So-Called Imperfect Aeration Symptoms of Post-Nasal Adenoids.—Dr. McKeown, of Manchester, read a short paper with this title. Headache, bad memory, stunted growth, etc., were usually attributed to imperfect aeration of blood, but he was of opinion that this explanation was not warranted, and he mentioned several reasons in support. Often the growths were too small to form sufficient obstruction. During sleep, the mouth being kept open, the intake of air must be ample. The symptoms were as a rule immediately relieved by operation. He referred to the anatomical relation of the growths to the sphenoidal and other sinuses, and pointed out that headache was not, as a rule, caused by imperfect aeration of blood. These considerations had led him to seek some other explanation, and he suggested that it might be found in reflex action.

Very few members had as yet arrived, and no discussion took place.

The Diastolic Expansion Movement of the Ventricles as a Factor in Compensation for Disease of the Mitral Valve.—Dr. Stacey Wilson, of Birmingham, followed with a long but interesting and carefully prepared paper on this subject. Unfortunately the time limit (fifteen minutes) did not give Dr. Wilson an opportunity of reading more than half the matter he had prepared, most of which was demonstrated by a series of cardiograph tracings. The following short epitome of his argument does poor justice to a valuable communication. He contended that the ventricular expansion movement during diastole was due to active expansion of the muscular fibres and not merely to passive dilatation. Experimentally it had been demonstrated (1) that the muscular wall of the ventricles remained active for an appreciable time after closure of the valves, and (2) Stefani had found that after section of the vagus less force was required to prevent diastolic expansion of the heart. The clinical evidence was scanty. His series of cardiographic tracings showed that the expansion rise was so great that it could not be caused by a mere elastic expansion; it must be muscular.

The President regretted that time did not allow a satisfactory elaboration of the interesting and valuable paper then being read. There was no discussion.

Pathogenesis of Gout.—Dr. Gore, of Whitchurch, read a paper entitled "A Toxin Theory of the Causation of Gout." Gout did not arise in all cases in which uric acid was found in excess in the blood, and, with the exception of the deposits in the joints, there was little evidence that uric acid was the cause of gout. He believed that the various manifestations of gout were the result of some morbid condition of the blood, which was probably brought about by a toxin developed in the alimentary canal from one of the bacilli commonly infesting the intestinal tract. A catarrh set up by the ingestion of unsuitable food would induce such changes as would enable the bacilli to exert their morbid influence through their toxins. He believed this theory would explain many of the aspects under which gout presented itself, and that it suggested a line of treatment aiming at the flushing and cleansing of the gastro-intestinal canal. His supposition would explain the baneful effects of lead which constricted the blood-vessels. He explained the concurrent presence of uric acid as due to the action of the toxins on the liver, and he believed that the specific alteration produced in the intestinal secretion by unsuitable diet was assisted by hereditary predisposition.

Dr. Samuel Bartow, of Norwich, agreed with Dr. Gore that gout must be due to some other cause than lithic acid, and he had always felt that. In his neighborhood lithic-acid calculus was extremely common; gout, on the other hand, very unusual. Therefore he maintained there must be some other factor, although he believed that this factor came into play only when uric acid was in the blood. He thought gout less common now than formerly, and supposed that that was due to people knowing better how to manage their diet.

Dr. Gordon, of Exeter, said that in Devonshire an exactly opposite condition of things obtained. Gout was common, but uric-acid stone almost unknown. He was in the habit of prescribing salicylic acid in some form for those irregular symptoms of gout such as headache, dyspepsia, and giddiness, and had had good results. He thought this supported Dr. Gore's contention.

Dr. Pope, of Leicester, thought that the fact that colchicum relieved only when it purged also bore testimony to the correctness of Dr. Gore's theory.

Dr. Garrett-Anderson, of London, found it impossible to accept the toxin theory for gout. She favored the chemical theory.

Subcutaneous Saline Injections in Pneumonia.—This paper, jointly compiled by Drs. Ewart and B. Percival, of London, was read by the former. He had thought it well, considering that treatment had as yet not reduced the mortality of pneumonia, to give a trial to this method, which had been introduced by Dr. Clement Penrose, of Baltimore. He thought cases might be roughly divided into three groups—those likely to recover, those almost certain to be fatal, and those in which there was uncertainty. It was to these very grave, but not hopeless cases that he had applied this method. It was not strictly empirical but had a scientific basis. It was well known that saline infusions were attended by success in cases of severe collapse. In pneumonia they were dealing with a disease in which sudden change for the worse, with collapse, often took place about the third or fourth day. This suggested applying the method of treatment which formed the subject of that paper. They, however, had considered it best to transfuse earlier, before the stage of possible collapse arrived, in the hope of supporting the system against its effects. A pint of decinormal saline solution was injected into the chest wall twice or thrice in the twenty-four hours, each operation occupying about an hour. He related six cases, only one of which appeared to benefit from the infusion. This case improved the day after the first injection and the temperature reached normal three days after. Of the other cases, all of which were fatal, one was complicated by typhoid, another by salpingitis and pleural effusion, two by alcoholism. Two had, in addition to the saline solution, ten per cent. peroxide of hydrogen. In none did the infusion produce any apparent favorable result, except, perhaps, to delay the fatal termination. They considered that

they could come to the following partial conclusions: that the infusions were not followed by any unfavorable consequence, but, on the contrary, they appeared to delay the fatal event; that possibly the bulk of saline solution should be increased; that the infusions were powerless to check fatal cases; that there was no effect on the changes in the lung; that the patients did not resent the treatment.

No discussion took place.

Progress in the Sanatorium Treatment of Consumption in England.—Dr. Jane Walker, of London, read a paper with this title. She believed that under favorable circumstances consumption could be cured in any climate, and advocated that the sanatorium treatment should be carried on in the climate in which the patient would afterward have to reside. She laid great stress on the importance of careful medical supervision in sanatoria. Those possessed of strength of will, wisdom, and equanimity of temperament did best. It was often very hard to tell people they were not yet well, although they might feel well. The general standard of health should decide the length of stay. It was very important to get cases early, as the chances of recovery from the second stage were not so good. She regarded inverse type of temperature, excessive pulse rate, and diarrhœa as indications for bad prognosis. When the temperature remained down and the patient gained weight she regarded the prognosis good. The management of these cases resolved itself into the exhibition of common sense on the part of all concerned. She held that Mr. Gibson, in the *Nineteenth Century*, erred in giving false hope to many by saying that all could be cured in sanatoria. She advocated sanatoria for tuberculous children and tuberculous pregnant women. Out of one hundred and seventy-seven cases passing through her hands, forty-five patients were cured and fifty-four improved; thirteen were losing ground, and seven died; twenty-nine were still under treatment, and she had lost sight of nine.

Dr. Chowry-Muthu, of Ilford, advocated open-air treatment for all infectious diseases. He had seen cases of scarlet fever, typhoid, and pneumonia all treated by this method with admirable results. With regard to consumption he considered that the sanatorium treatment gave the best results for the majority. Under the old methods patients did what they liked; now they placed themselves under the generalship of a medical man, and he believed that was the secret. Three things influenced the progress of these cases especially, vitiation of the stomach by toxins, bronchial catarrh, and strong east winds.

Dr. Burton-Fanning, of Norwich, was sure that wisdom on the part of the patient was of great value, and was glad Dr. Walker had drawn attention to that. He considered no thanks were due to Mr. Gibson. The latter, in his article in the *Nineteenth Century*, spoke of cure being effected in three months; in his experience, one year was the shortest stay a patient should make. Mr. Gibson spoke of ninety per cent. of cures. It would be more correct to say ninety per cent. of the patients improved. He believed everything depended upon early treatment, and for this reason he considered the stethoscope of less value than the thermometer, the laryngoscope, and staining reagents. He agreed that climate was of little importance, and commended Dr. Walker's statement that elaborate common sense was what was of most value.

Dr. St. Clair Thomson, of London, speaking as an official, urged the importance of making people understand the necessity for medical supervision. A retired tradesman had written to him and said he had taken two roomy cottages and had placed all the cases of consumption he could find in them; was there anything else he could do? He thought that cases had sometimes been kept too long in sanatoria to the detriment of others. A wise American had once remarked that we must not get hold of the wrong case and put it in the wrong place, until death resulted; but we must get the right case, and put it in the right place, until recovery took place.

Consanguinity as a Factor in the Etiology of Tuberculosis.—Dr. Charles Davies, of the Isle of Man, read this paper. After bringing evidence from various authors to show that it had been commonly known and observed from early times that children sprung from in-and-in marriages were of inferior energy, he directed attention to the condition of things existing in the Isle of Man. The Manx, an isolated being, resented the introduction of strangers, and, further, the dwellers in the north not only held the southerners of the island in aversion, but there were natural physical conditions which formed a barrier between them. In addition it was rare for migration from village to village to take place. The consequence was that undoubtedly families had married and intermarried with their immediate neighbors again and again. There was no exaggeration in saying that three parts of the inhabitants were related to one another. The Manx people had then attained to a very high degree of consanguinity. Did ill-effects result? There was undoubtedly a high phthisis rate, viz., 25.7 per 10,000 living, and he believed this was accounted for by in-breeding. The temperature of the island was equable; fogs were unknown, sunshine was abundant, and he considered the climate to be eminently suitable for the treatment of lung diseases. The soil was fairly dry and well drained, the natives were well nourished and happy and contented. Their principal occupations were healthy. The dwellings were no worse, from a sanitary point of view, than those of their class in England. He was driven, therefore, to conclude that there must be something in the constitutional idiosyncrasy of the people that rendered them peculiarly liable to tubercle.

Dr. Sommerville, of London, asked if the same result had been noticed among the royal families and nobility of Europe.

Dr. St. Clair Thomson wished to thank Dr. Davies for his interesting paper. It was at his suggestion that Dr. Davies had come from the Isle of Man to make that contribution to the etiology of phthisis.

Dr. Barton thought that consanguinity *per se* might not be the cause. Was it not rather due to tubercle attacking a community in which intermarriage was common? At Clovilly, where there was much inbreeding, there was no tubercle.

Dr. Gore suggested that the condition of the cottages might have an influence, as he believed was the case in Ireland.

Orrhotherapy of Malignant Endocarditis.—Dr. Ewart next related a case of fatal malignant endocarditis and right embolic hemiplegia apparently due to infection from dental caries and stomatitis, treated by anti-streptococcic serum and by saline infusions. A man aged twenty-six years was admitted to St. George's Hospital on April 10th, having been seized suddenly with aphasia and right-sided paralysis. On admission, the only thing noticed after careful examination was a systolic mitral murmur. His temperature was 101° F., and he had albumin in his urine. On April 13th he became worse and died suddenly. There was no delirium, but the man was nervous; he understood what was said to him, but had difficulty in making his wants known. The cardiac signs had varied since admission. A diastolic murmur had been heard over the pulmonary valves and a double murmur at the apex. On this account the diagnosis of ulcerative endocarditis was made. For treatment he was at first placed on a mixture containing perchloride

of mercury. Subsequently five injections of anti-streptococcus serum were administered, and he was given four saline infusions, while finally large doses of quinine were tried. A question of source of infection had been before their minds, and a very thorough investigation was therefore made. They found only stomatitis from decayed stumps with very intense fetor. The glands were not enlarged. A post-mortem examination was made forty-two hours after death. The aortic valves appeared greatly diseased with ulcerative vegetations, the liver was nutmeg, there was an infarct in one kidney. There was an embolism of the left middle cerebral artery with softening of the brain tissue. Van Jurgensen, Ludwig, Herzog, and others made no reference to any portal of infection in their recorded cases; they called them primary ulcerative endocarditis. Some authors, however, in reporting cases, had mentioned certain septic conditions incidentally. Gibson, for example, had related a case in which middle-ear disease was present. Dreschfeld came nearest to pointing to the mouth as a possible route for infection. If no examination had been made in the case he had related that day, he supposed it would have been put down as primary disease of the valves; but he believed that, having excluded all other possible sources, that case depended upon an organism existing in the mouth.

Dr. Coldstream, of Florence, remarked that he had published a case of ulcerative endocarditis which resulted fatally on the fourth or fifth day after a gumboil, associated with a bad tooth, had been incised.

Dr. Sommerville referred to cases which led him to suppose the cause of infection might have been an unclean condition of the mouth.

Dr. Stacey Wilson mentioned cases associated with middle-ear disease which had come under his notice.

With Dr. Ewart's reply the proceedings of the section terminated.

SECTION OF TROPICAL DISEASES.

First Day—Wednesday, August 1st.

President's Address.—Col. Kenneth Macleod, president of the section, gave an opening address on "The Scope and Aim of the Section's Work." A knowledge of the pathology and pathogenesis of disease, he said, must obviously precede and guide preventive and curative effort; and it could not be too loudly proclaimed that this knowledge could be obtained only by systematic scientific research. The days of casual and statistical observations and dissertations had gone, and it was now universally understood that nothing would avail for the solution of pathological problems except the undistracted work of trained agents provided with ample opportunities, facilities, and appliances. The recent history of malariology, he continued, was a signal illustration of the dependence of sanitary and therapeutical endeavor on pathological discovery. Laveran in 1880 furnished the key to the morbid processes which in malarious disease took place within the body by the discovery of the plasmodium malariæ. Manson and Ross pioneered the brilliant investigations which had revealed one, if not the one, means by which this organism left the infected subject, lived and bred in outer nature, thus compassing the communication of what must now be admitted to be an infective disease. This knowledge was being at the present time turned to practical account, and it explained and gave precision to methods of prevention and cure which had previously been resorted to empirically. Koch had been attacking the plasmodium within the human host, and claimed, by destroying it in that phase or stage of its existence, not only to cure the individual but to reduce greatly, or altogether abolish, the prevalence of malarious disease in the community. Sambon and Low in Italy were addressing themselves to the extrasomatic life of the parasite, and endeavoring by special contrivances and precautions to cut the morbific circuit outside the body. The results of their labors would be eagerly watched, as they would contribute an important aid to the solution of the question whether the Anopheles was the only medium of malarious infection, and, if so, whether this occurred invariably by inoculation. That typhoid fever existed in South Africa, and was apt to prevail in South African towns and cantonments during the summer months, was well known, and its appearance among the troops engaged in this war was fully anticipated; but the excessive prevalence of the disease in a country and climate with a reputation for exceptional healthiness had come, he said, as an unpleasant surprise. No doubt the circumstances and exigencies of warfare were mainly responsible for the heavy tribute of sickness and death which the fever had levied. War shared with famine the malignant power of enhancing the susceptibility to whatever infection happened to be present at the place and time. Malaria, cholera, yellow fever, and dysentery had on many occasions been stimulated into disastrous activity by war. So with famine; malarious disease, smallpox, diarrhœa, dysentery, and relapsing fever had attended or followed it, and at the present time cholera and plague were raging among the famine-stricken in India. It was important to note, the speaker continued, that a very marked contrast existed between the ordinary incidence and mortality of the disease in temperate and tropical or sub-tropical countries—in England and Canada on the one hand, and in India and Egypt on the other. A similar contrast appeared in the French army stationed in France and in Northern Africa. How much of this great excess was due to tropical conditions, topical and climatic, and how much to remediable sanitary defects, it was not easy to say. But, side by side with the excessive suffering of the army in India, we were confronted with the remarkable fact of the immunity of the native population. Whether a similar immunity existed among indigenous races and habitual residents in South Africa was an interesting question. Evidence seemed to indicate that it was so. The native immunity in India, though not absolute, was undoubted; its cause had not been satisfactorily ascertained. It had been attributed to habituation to minute dosage of the contagium, to protection conferred by attack during infancy and childhood, and to racial resistance acquired in the course of generations through both these influences. Some experiments by Freyer and others indicated that natives gave positive reactions to Widal's test; but more extended and exact investigations on this point were desirable. It was quite certain that the immunity was not due to superior sanitary conditions. Whether a similar immunity—temporary or permanent—could be engendered in European subjects by a process of inoculation such as had been devised by Professor Wright, of Netley, and practised on a large scale among soldiers proceeding to the seat of war, was a question the reply to which was awaited with eager anxiety. Some figures obtained from Ladysmith had been published by Professor Wright, which seemed to show that some immunity was conferred by these inoculations, but, though encouraging, they were by no means demonstrative. The persistence of plague in India and the appearance of the disease for the first time south of the equator—in Mauritius, South Africa, South America, and Australia—were events deserving of special notice. The disease had during its present prevalence confined itself mostly to warm and hot countries, and, though not exclusively a tropical disease, nor apt in

the tropics to be at its worst when conditions were most typically tropical, it appeared to find in tropical countries and circumstances the most favoring environment. It was curious to remark that, while in India natives appeared to be readily susceptible to the infection of plague. Europeans, though not absolutely insusceptible, exhibited a comparative immunity—the reverse of what happened as regarded typhoid fever. The work of this section, Dr. Macleod said, in concluding his remarks, had to do not only with exclusively tropical diseases, many of them strangely named and imperfectly investigated and understood, which might be encountered and contracted in hot places where Europeans were compelled to reside for purposes of protection, administration, or commerce, and which were not as a rule met with outside of the tropics. More important were those diseases, originally or essentially tropical, which might be disseminated by intercourse with the tropics, and might prevail for a time in extra-tropical localities in which they were not habitually present. And, finally, there were the diseases which were not specially tropical, but which were liable to be aggravated in prevalence or severity by tropical conditions. These three classes represented a wide field of research, and, in addition, interesting questions arose regarding diseases which, common elsewhere, were rare or unknown in tropical countries.

Quinine; its Action and Value.—Dr. Andrew Duncan opened a discussion upon the use of quinine as a prophylactic and as a curative agent. He said that in the hands of French physicians quinine was found to be of some prophylactic value in the milder forms of malarial fever, but in pernicious varieties it was wellnigh useless. The general conclusions arrived at by Russian and Austrian military surgeons were that quinine had but little, if any, value as a prophylactic. In America Dr. Bryan stated that cinchona preparations had a markedly prophylactic action. The last Surgeon-Major Parke, of the Stanley expedition in search of Livingstone, gave the officers four grains of quinine daily for ten days before entering the mouth of the Congo. During a subsequent journey of three hundred and fifty miles through one of the most unhealthy regions of the world only two officers contracted fever. The speaker's own experiences in India afforded support to the belief that the giving of quinine was a preventive to malaria. In 1896, of fifty men of the Second Goorkha Rifles who took three grains of quinine daily none had fever, whereas among the men who took no drugs 6.5 per cent. had malaria; in 1897 the same experiment was tried again, when the results were, no malaria among the quinine takers and 9.8 per cent. among the non-quinine takers. During the Malay war the prophylactic benefits of quinine were not marked. West African experiences were varied. Harvey found that the sailors who took quinine had as much fever as the men who did not take it. During the Ashanti wars of 1893 and 1896 quinine as a prophylactic proved of no benefit. An inquiry in connection with this subject was promoted by Mr. Chamberlain and Dr. Manson in West Africa. The benefit of quinine as elicited by this inquiry seemed to be pronounced, for in 87.7 per cent. of those who used it as prophylactic it was efficacious. Dr. Duncan then reviewed the action of several reputed antimalarial drugs. Arsenic as a prophylactic afforded conflicting evidence. In Italy it had been moderately successful, in India it had proved very disappointing. The most eminently successful experiment seemed to have been made by Dr. Ralph Leslie in the Congo Free State, where arsenic was administered during fifteen days every six weeks, and every one who took it was rendered immune to fever. Narcotine seemed of little value as a prophylactic. As a cure for malarial attacks quinine gave by far the best results, only 2.05 per cent. of failures. Next to quinine as a curative came nim bark in doses of ʒi. thrice daily; failures were eighteen per cent. Berberis had fifty per cent. of failures. Narcotine, kreat, and inderjas seemed to be unreliable as either prophylactic or curative agents.

Maj. W. J. Buchanan reported an experiment on a large scale. At six of the large jails of India the prophylactic issue of quinine had been tried for five years past. In some instances the results had been tested by control experiments. At the Mymensingh jail the result was "diminished fever"; at the Rajahmundri jail, one of the most malarial jails in India, quinine as a prophylactic was useful in the case of those who had not been previously exposed to malaria; those who contracted fever had it more mildly; the duration was shorter and the recurrences were fewer when the drug had been taken previously as a preventive. At the Rajshaye jail Lieutenant-Colonel French reported strongly in favor of quinine as a prophylactic during 1896 and 1897, but he changed his opinion in consequence of the experiences gained during 1898. At the Bankura jail the prophylactic issue of quinine had distinctly beneficial results; at the Huzaribagh jail, Major Maynard gave it as his opinion that cinchonidine given in six-grain doses daily was useful as a prophylactic, and as a beneficial agent should attacks of fever come on afterward. Major Buchanan's experience at the Bhagalpur jail proved negative, the quinine takers and those who had not taken the drug being equally affected. Major Buchanan had never seen hæmoglobinuria or other evil effects from taking quinine.

Dr. Fielding Ould, of West Africa, said that since Koch's statements about quinine the Europeans on the West Coast entertained, many of them, a dread of the drug. Quinine acted by staying the development of the malarial amœbæ: it might do so by binding the oxygen to the hæmoglobin more closely and thus depriving the parasite of the oxygen necessary for its growth. Quinine could be in no sense a preventive, it could deal with the parasite only when it existed in certain stages in the blood; it could not prevent the entrance of the parasite into the blood. He quoted an experiment of Bignami's in which blood rich in parasites but impregnated with quinine was incapable of reproducing malaria when injected into a healthy person. Of the methods of administration that by the mouth was perhaps preferable unless gastric catarrh was present, when it might be given by the rectum or hypodermically. The prophylactic use of quinine was in many instances harmful by upsetting digestion; and it was persons who suffered from gastric catarrh or hyperæmia of the liver who were wont to be most severely attacked by malaria; in them the pernicious forms of malaria, the bilious remittent and hæmoglobinuria, were apt to develop.

Dr. Patrick Manson said that the reputed prophylactic action of quinine was but a phase of its therapeutic action; it was the application of the drug to the parasite and not an immunizing of the body against the parasite that characterized the action of quinine. Just as some varieties of the parasite were highly amenable to the drug given therapeutically, similarly its prophylactic power would be greater against such. Dr. Manson recommended that future experiments in prophylaxis be made with the aid of the microscope, and in reference to the particular type of malarial parasite it was used against.

Lieutenant-Colonel Mursden stated that he had invariably given quinine, both as a prophylactic and as a therapeutic agent, for the last twenty years, and the results had nearly always been satisfactory. He described the only case in which he had seen quinine

cause hæmoglobinuria as that of a German missionary, who every time he took quinine declared that hæmoglobinuria supervened, and when the drug was administered by the speaker the urinary trouble developed.

Mr. D. C. Rees, of London, gave his experience of quinine as a prophylactic in Nigeria. He came to the conclusion that five grains administered daily, although it did not reduce markedly the number of attacks of fever, tended to lessen the severity and also the case mortality. He advocated introducing the needle of the hypodermic syringe into the muscles when administering quinine by this method; when introduced beneath the skin only, suppuration was apt to follow.

Dr. C. F. Harford-Battersby, of London, believed strongly in the prophylactic value of quinine. Although quinine might cause hæmoglobinuria, he did not believe it could cause hæmoglobinuric fever. He held that there were many minor ailments attributable to malaria, such as vomiting, neuralgia, etc., which quinine would relieve.

Major Wilson did not find in the Ashanti expedition of 1895-96, nor on the Sierra Leone coast, that quinine held much prophylactic value. He had used the hypodermic injection of quinine in many instances without causing local inflammation.

Dr. B. S. Ringer, of Canton, China, described a case of quinine blindness (occurring in malaria), which disappeared by treatment with ten-grain doses of potassium iodide.

Lt.-Col. B. C. Maitland asked for information concerning the use of methylene blue in malarial fever. During an outbreak of malaria he gave it in alternate cases with quinine and found methylene blue gave the better results. He found little danger in giving quinine in pregnancy, and he had administered it without inducing abortion at any and every stage of pregnancy.

Mr. James Cantlie, of London, related a case of fever in a child four months of age. The child was born in England, while the parents were at home on a holiday from China. The fever continued for six weeks, and it was only when the mother, who was nursing the child, and the child took quinine that the fever disappeared.

Dr. Henderson, of Shanghai, stated that the benign tertian was the usual malarial parasite met with in Shanghai practice, and that it readily yielded to quinine. He believed quinine to be a decidedly dangerous drug in pregnancy, and he had seen miscarriages traceable to its administration. With opium, or better still with chlorodyne, some of the danger of quinine to pregnant women might possibly be minimized.

Major Ronald Ross, of Liverpool, drew attention to the circumstance that in old cases of malaria there might be a secondary form of fever, due to enlargement of the liver and spleen, not directly due to the presence of parasites and not amenable to quinine. Major Ross advocated the exhibition of quinine for three months after infection, and believed the best form of administration was in solution by mouth.

Dr. Guthrie Rankin, of London, described a case of hæmoglobinuric fever developing in about fourteen months after settlement in Central Africa. The man returned to England, had a mild attack of hæmoglobinuria, and after four months went back to Africa. During his second term of residence there, extending over two and a half years, he took quinine daily in teaspoonful doses, and never had a return of malarial fever.

Lt.-Col. Oswald Baker, of London, believed the reason of quinine failing as a prophylactic was that it was not given in sufficient doses. He was of opinion that the prophylactic dose should be the same as the curative dose.

Col. H. Macleod, of Netley, pointed out the importance of using the microscope as a guide and check during the administration of quinine. It had been asserted that malarial parasites might exist in the blood without causing pyrexia, and it was necessary to ascertain the infection of the community before coming to a conclusion as regarded the prophylactic use of quinine. Colonel MacLeod referred to the distinction to be drawn between hæmoglobinuria and hæmoglobinuric fever. The former was caused by many drugs, but the latter seemed to be a specific disease.

Notes on the Etiology of Filariasis.—Lieutenant-Colonel Maitland referred to the observations made by Dr. G. C. Low concerning the presence of the filiarial parasite in the proboscis of the mosquito, and the probability of the infection of the human being by the bite of the mosquito. He regarded the evidence in favor of this theory as presumptive only and opposed to well-attested evidence. He drew attention to the extraordinary immunity of Europeans to filariasis in districts where the natives were extensively infected, and regarded the fact that Europeans boiled or filtered their drinking-water as an argument in favor of water being the medium of infection in filariasis. The speaker thought it quite possible that the young filaria might pass from the mosquito's proboscis into water instead of directly into the blood.

Metamorphosis of the Filaria Sanguinis Hominis in Mosquitos.—Capt. T. P. James read a paper in which he drew attention to the difference in time required for the metamorphosis of the filaria in mosquitos observed by Bancroft and Manson, and it would appear that the period of such metamorphosis was not yet determined definitely. In Bancroft's experiments and in those undertaken by Captain James, the female Culex was employed. The insects were bred from larvæ placed under the mosquito curtains of a filariated man's bed, and when caught they were transferred to bottles in which ripe bananas were hung. Against the water-borne theory of infection Captain James advanced the argument that the filaria died in two and a half hours in pure water; and therefore too short an existence was allowed to insure continuance of the species. The speaker favored the idea that the filaria was carried to the human being by the bite of either the Anopheles or Culex.

Dr. Manson wished to state that the discoveries of Dr. Low and Captain James were made independently of each other, and that both observers were entitled to have their names associated with the establishment of the fact that the filarial worm could find exit by way of the proboscis of the mosquito. He regarded the relative immunity of Europeans to filarial infection as due to the use of mosquito nets and their better sanitary surroundings compared with those of the poor natives. The process of richly infecting a human being by filaria probably involved a considerable time; the individual required possibly to be bitten many scores of times by filaria infected mosquitos before the embryos appeared in sufficient numbers to cause pathologically lesions of any clinical magnitude. He drew attention to the analogy between filariasis and malaria. In both diseases a parasite was removed from the human blood by the mosquito; they both developed in the mosquito's tissues, both probably quitted the mosquito via the proboscis, both were inoculated by the mosquito bite, both exhibited a remarkable periodicity in the human blood, and both gave rise to recurring fevers.

Mr. D. C. Rees said that although both Dr. Bancroft, of Australia, and Captain James seemed disinclined to believe that filaria nocturna cast its sheath in the mosquito's stomach, he thought there could be little doubt that it did do so. Several specimens in his possession showed that ecclysis has taken place, for the filaria and its sheath could be seen side by side.

Major Ross referred to the case of an Englishman living in the West Indies who suffered from elephantiasis which he ascribed to the bite of a mosquito.

Hot-Weather Diarrhœa in India.—Maj. W. T. Buchanan read a paper drawing attention to a very severe form of diarrhœa which was not cholera, but in many cases closely resembled it. After describing the sudden onset, the watery stools, the collapse, the cyanotic appearance of the patient, occasional suppression of urine, etc., he said he thought the disease bore the same relation to cholera in India as did summer diarrhœa to cholera nostras in England. He suggested the name "thermic diarrhœa" for the complaint. The disease, especially in old people, was occasionally fatal. The treatment consisted in boiled milk, brandy, and the tinctura chloroformi et morphinæ Co. B.P.; as the diarrhœa subsided, a dose of castor oil hastened recovery.

Colonel Macleod remarked that Major Buchanan's paper raised two questions: First, as to the distinction between cholera nostras and cholera Asiatica, and, second, what the organisms or toxins were which gave rise to cholera nostras. The form of diarrhœa mentioned was very common among children in India.

A Note on a Case of Blackwater Fever.—Dr. George Thin, of London, reported the case of a man who died of blackwater fever in Central Africa. Specimens were forwarded to Dr. Thin by Dr. Douglas Gray for examination. Dr. Thin's conclusions were that the patient died of acute malarial fever in which the hæmoglobinuria was a concomitant symptom. The presence, condition, and extent of the pigment in the liver and spleen showed the recent existence of the parasite in great numbers at some point of the blood circulation.

Dr. Manson remarked that, although he inclined to the belief that hæmoglobinuric fever was an expression of malarial fever, he did not think we were justified in jumping at such a conclusion merely because the malarial parasite was found in a hæmoglobinuric patient's blood. It would be strange were post-mortem evidence of malarial infection not found in persons dwelling in so highly malarious a country as British Central Africa, whatever the cause of death.

Mr. D. C. Rees stated that he had examined specimens from the same patient upon which Dr. Thin had reported, and he had come to an exactly opposite conclusion to that arrived at by Dr. Thin.

The Diseases of Goorkhas.—Dr. Andrew Duncan said that malarial fever of an intractable form seemed to prevail among the soldiers of the Goorkha regiments he had been quartered with. He found administration of quinine by the rectum was more efficacious than by the mouth. Phthisis seemed also to run a peculiar course, passing from mild symptoms to a severe and suddenly fatal form. Mumps, measles, and ophthalmia were prevalent. Enteric fever, contrary to popular belief, was not a common disease among Goorkhas; in fact, he had seen only one case. In reply to Mr. Cantlie, Dr. Duncan stated that he had never seen scarlet fever among Goorkhas.

Second Day—Thursday, August 2d.

Ankylostomiasis.—Major G. M. Giles opened the discussion on ankylostomiasis by communicating a paper in which he referred to: (1) the history of our knowledge of the disease; (2) his own researches into the life history of the free stage of ankylostomum, by which he established the fact that the rhabdites can live and multiply freely in fecal matter; in other words, that it was a case of heterogenesis or dimorphism. (3) He then dealt with Dr. Sonsino's criticisms as regards the accuracy of his observations. Dr. Sonsino held that the organisms described by Major Giles were rhabdites terricola or other free nematodes, and that the appearances were really the free form of rhabdomena intestinale. To these criticisms Major Giles gave a distinct negative as to their potency. (4) Major Giles next discussed the question of the harmful versus the harmless nature of the ankylostomum. He held that the parasite was responsible for a formidable mortality, and for a great amount of chronic sickness.

Capt. A. T. Fearnside continued the discussion. He told of a systematic research for the ova of the ankylostomum parasite among the convicts and new arrivals in the central prison at Rajahmundry in India. He found that of six hundred and seventy-eight new arrivals at the prison four hundred and sixty-two, or 68.1 per cent., harbored the parasite. In another group of observations, the speaker found seventy-two per cent. infested, yet they remained in good health. About thirty-five per cent. harbored the ankylostomum and ascaris lumbricoides simultaneously. At one hundred and five post-mortem examinations at the jail, 74.3 per cent. revealed the presence of the ankylostomum. He held that post-mortem evidence went to show that the effects of the ankylostoma were for the most part secondary and not primary, and that it was only when the ankylostoma attacked a person already weakened by malaria or other illnesses that ankylostomiasis developed.

Dr. Leonard Rogers read a paper on "The Classification and Differential Diagnosis of Ankylostomiasis with Special Reference to the Type of the Anæmia." The question of the relation of kala-azar to ankylostomiasis was discussed by Captain Rogers, and he agreed with Major Ross that kala-azar had a malarial rather than an ankylostomian basis. He regarded ankylostomiasis as a disease characterized by anæmia produced by long-continued small losses of blood through the gastro-intestinal mucous membrane caused by the presence of several hundreds of ankylostoma acting for many months, or by still larger numbers acting for a shorter time.

Lieut.-Col. Oswald Baker described the condition induced by the ankylostoma in severe form as being practically identical with that of a person bled to the verge of death. He established the fact that the ankylostomum was extremely prevalent throughout the province, and considered the prevalence of ankylostomiasis to be directly and indirectly responsible for a high mortality. He attributed the wide distribution of the disease to be due to the habits and customs of the Burmese, especially as regards their mode of eating their food.

Dr. Manson remarked on the fact that the rhabdomena intestinale was so seldom found by Major Giles in Assam, considering that it was so frequently associated elsewhere with the ankylostomum, and that the climatic and other physical conditions closely resembled those in Cochin-China where the parasite was extremely common. The speaker had twice encountered ankylostoma in the stools of Englishmen who had returned to this country from the West Indies. He disagreed with a remark made by Dr. Fearnside in regard to the inefficiency of thymol as an anthelmintic, and stated that thymol rarely failed, if given in adequate and rapidly repeated doses. He referred also to the virtues of betel-nut taken by the natives of Assam, Burmah, and Malaya as a prophylactic against ankylostomum. He believed that the parasite was generally acquired by way of the food.

Major Ross remarked that he had carefully followed Major Giles' investigations on the rhabditiform stage of the parasite, and considered his conclusions sound. He regarded the well-known fact that the disease was present among earth-workers as an argument in favor of Major Giles' statements. He scouted the idea that

the ankylostoma parasite was harmless, and entered a plea for the much more general use of the microscope for the detection of the ova in localities where the worm was prevalent.

Mr. Cantlie stated that, stimulated by the researches of Dr. Walker in Borneo concerning the association of the ankylostomum with beri-beri, he had carried out prolonged examinations in Hong Kong, but failed to find the parasite in cases of beri-beri.

Tropical Abscess of the Liver.—Col. Kenneth Macleod, of Netley, read a paper on "The Management of Lung Lesions Consequent on Liver Abscess." The frequency of liver abscess pointing in the direction of the thorax, and opening either into the pleural cavity or into the lung, was referred to. When such an event occurred a free opening into the pleural cavity must be made, with resection of a rib if necessary. He pointed out the futility of operating upon an abscess of the liver after expectoration of liver pus. In all such cases the condition ought to be approached by way of the chest, and the lung treated as the offending organ; for very soon after the pus had found evacuation by way of a bronchus, the liver abscess commenced to heal and was not infrequently healed altogether, the patient succumbing to the lung lesion. He advocated leaving the liver to take care of itself in such cases, and the treatment should be confined to the relief of the lung.

Mr. James Cantlie, of London, read a paper on "Subhepatic Abscess." By subhepatic abscess he meant a collection of pus between the capsule of the liver and the under surface of the liver substance. The abscess tended to point in the epigastrium, and was probably due to a lymphangitis, and was not associated with either dysentery or any other pronounced intestinal lesion. He had been able to verify the existence of subhepatic abscess in a case in which laparotomy was performed, and he had seen two or three cases in which the clinical evidence was pronounced.

Dr. W. Johnson Smith, of Greenwich, continued the discussion with a paper on "The Diagnosis and Surgical Treatment of Tropical Liver Abscess." In regard to surgical treatment, he said he preferred exploratory puncture to laparotomy as a means of diagnosis. He had met with almost invariable success by puncturing the liver, and had never seen any untoward effects from it. Laparotomy, under the most favorable circumstances, had certain inconveniences and after-troubles when employed as a means of diagnosis. When treating the abscess by trans-pleural incision there was great danger of opening the cavity of the pleura. When the diaphragm was so pressed upward as to bulge into the wound, the pleural layers might be so approximated that one did not gain entrance to the cavity, a most fortunate circumstance.

Staff Surgeon P. W. Bassett Smith, of Haslar, reported a case of abscess of the left lobe of the liver, with remarks particularly referring to its amœbic causation. The abscess in this instance occurred in a man in England who had not been abroad for two years. The hepatic abscess followed quickly after an attack of dysentery. Amœbæ coli were abundantly found in the pus, to the exclusion of pyogenic bacteria. Owing to the existence of the pus in the left lobe of the liver the abscess was not found by exploratory puncture until quite late in the illness. Post-mortem an abscess was found on the right lung, not directly communicating with the liver abscess cavity.

Dr. Manson referred to the heroic nature of the operation for liver abscess practised by most surgeons in England, and thought that by the trocar and cannula more satisfactory results were obtained. He did not regard the presence of the amœba coli in the sputum as an indication of pus in the liver, he had never met with it. He failed to understand the cause of the serious hemorrhage met with during hepatic puncture by Bombay surgeons.

Major Ross had seen a case of hepatic abscess in Liverpool in which leucocythæmia but no evidence of malaria was present.

Mr. Cantlie said he had followed Dr. Manson's plan of treating liver abscess by the trocar and cannula and the insertion of a large drainage tube into the cavity, with success. He stated that he had studied the dangers from hemorrhage during hepatic exploration, and had from a frozen section of the body come to the conclusion that in a chest of thirty-two inches circumference it was not safe to penetrate farther into the liver in a vertical direction from the surface than three and three-fourths inches.

Colonel Macleod agreed with Dr. Manson that the plan followed by most surgeons was too severe. He mentioned a case in which after laparotomy the surgeon failed to find pus in the liver, yet the abscess burst into the bowel within three days after the operation. The trans-thoracic incision, with the removal of a rib and stitching of parts together, was an unnecessary proceeding unless the pus was actually in the pleural cavity.

The Cyprus Sphalangi and its Connection with Anthrax was the subject of a paper communicated by Dr. George A. Williamson, of Cyprus. He said that the so-called sphalangi was an insect resembling an ant belonging to a genus of sting-bearing hymenoptera, called mutilla. The bite of this insect was considered in Cyprus to be the means of carrying anthrax to human beings from animals dead of the disease. After stinging the local symptoms were a circumscribed induration and widespread œdema with toxic general symptoms. The discharge from the puncture had been found to swarm with anthrax bacilli. The treatment consisted in destruction of the indurated tissue by the cautery and hypodermic injections around the part of a solution of mercuric chloride and potassium iodide.

Some Suggestions for the Improvement of Sanitary Medical Practice in the Tropics was the subject of a paper by Maj. Ronald Ross. He advocated (1) the formation of small up-to-date libraries in the large towns in our colonies; a better supply of microscopes; (2) the necessity for improved municipal sanitary regulations; (3) the desirability of securing organization in the matter of research; (4) the importance of establishing a central scientific authority.

Dr. Mullick, of London, said there was urgent necessity for the appointment of specially trained investigators to fill the chairs in the medical schools of India.

Colonel Macleod pointed out the difference between a teacher and an investigator; seldom was the power of imparting knowledge and investigation met with in the same individual, and the first thing required of the lecturers in our schools was that they should be good teachers.

Third Day—Friday, August 3d.

Yaws.—Mr. Jonathan Hutchinson opened the discussion on yaws. He showed a man, a European from the west coast of Africa, believed to have contracted yaws. He regarded yaws as the parent of syphilis, and adduced many arguments in favor of the contention. In Fiji, where yaws prevailed, there was no syphilis, and he argued that the presence of yaws prevented infection by syphilis. Mr. Hutchinson denied the statement that there was no primary sore in yaws. He believed that sailors and others becoming infected by yaws abroad came back to this country with the signs and symptoms of syphilis, the cause of

the slight differences in symptoms being probably accounted for by climate.

Dr. Davies, of Samoa, said that in Fiji children only were attacked by yaws, and he failed to see how the disease could be acquired by sailors. In Fiji and Samoa the natives considered yaws in children in the same light as we in Britain regarded measles—that it was almost a certainty to have the disease, and the sooner it was got over the better.

Dr. Manson considered Mr. Hutchinson's views on yaws open to question and thought it strange that inoculation by yaws did not protect one from syphilis, and vice versa, if, as Mr. Hutchinson suggested, the primary poisons were identical. Why yaws was not seen in England was to be explained in the same way as the absence of many other skin affections of tropical origin, viz., that a high constant temperature was necessary for its continuance and development.

Mr. C. Rees said that he saw syphilitic cases and cases of yaws side by side in West Africa; that in the Hinterland yaws was common but syphilis unknown, and that the natives of the West African coast regarded syphilis as a new disease.

Colonel Macleod stated that he thought the case shown by Mr. Hutchinson was a case of syphilis, and all present agreed with him.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 25, 1900:

	Cases.	Deaths.
Tuberculosis	189	115
Typhoid fever	51	14
Scarlet fever	51	3
Measles	37	5
Diphtheria	120	28
Laryngeal diphtheria (croup)	6	4
Cerebro-spinal meningitis	0	7
Chicken-pox	1	
Smallpox	0	1

Antivivisectors in Sheffield.—The Sheffield correspondent of the *British Medical Journal* says: "The antivivisectors after a lull are again on the war-path. The walls and hoardings of Sheffield are placarded with 'torture' pictures calculated to hold the medical profession up to opprobrium and possibly to arouse the sympathies of the ill-informed. The campaign is fairly launched against the holding of a license at the University College. An office has been started, and signatures are solicited for a petition for the withdrawal of the license. An active canvass is also being promoted with the same object in view."

Climate of Pekin.—A well-informed journal, referring to the configuration of the country and the weather generally experienced in the neighborhood of Pekin, says: "The most of the territory east and west of Pekin in which the earlier part of the Chinese campaign will have to be carried on is flat and low-lying, much of it subject to yearly devastation by the overflow of the rivers. In winter the cold is frequently very severe, more so than in New York, which has nearly the same latitude as Pekin, and it is probably in anticipation of a campaign during the coming cold season that the British government called for tenders for the supply of fur capes for a considerable number of troops. At present the heat in the flat country east of Pekin is great, and the season rainy, but in view of a prolonged resistance by the Chinese it seems desirable that the same preparations should be made for the comfort of our troops."

Contagiousness of Smallpox.—Smallpox is probably more contagious than any other disease. As reported in the British Local Government Reports for the periods 1884–85, it was found by Dr. Power (the now chief medical officer of the board) that the disease was liable to be communicated under favoring conditions at the distance of a quarter of a mile. He showed that if the district in which the Fulham Hospital was situated were divided into zones by means of circles drawn upon a map of the locality, with the hospital in the centre, with radii of a quarter of a mile, three-quarters of a mile, and one mile distant respectively, and an enumeration made of all the houses in each belt and also of all houses invaded by smallpox, the proportion of invaded houses diminished as the distance from the hospital increased, and this relation held good in each "quadrant" of each zone. Within the quarter-mile zone there was only one approach to the hospital, and this was in the northwest quadrant. The distribution of cases in the several quadrants was not such as to suggest any relation to lines of traffic or ambulance routes. He concluded that diffusion occurred only when acute cases were aggravated and perhaps only under certain atmospheric conditions.

State Sanatoria for Consumptives.—Dr. Edward Otis thinks that State sanatoria should be erected by State appropriation, and at least partially maintained from the same source. A portion of the expense could be collected in some cases from the patient through his friends, or by private charity, or defrayed by the city or town from which he comes. Of course, the entire maintenance could be provided for by a per-capita tax on the locality from which each patient comes, as suggested by the New York board of health, but in the opinion of Dr. Otis a certain yearly appropriation should be made by the State, if not directly for maintenance purposes at least for investigations in bacteriology, pathology, and treatment of tuberculosis, which would indirectly benefit not only the State but the public generally.

Arsenic in a Popular Purgative.—Some little time ago a rumor was made public in Great Britain which caused widespread alarm. The report ran that a large firm of manufacturing chemists had for several months been sending out a granular phosphate of soda which was afterward found to contain a dangerous amount of arsenic. The firm issued a circular to chemists stating "that the phosphate of soda lately supplied by them contains a dangerous percentage of an arsenical preparation." They further admit that this defect applies to all phosphate of soda supplied from November 15, 1899, until the end of April, 1900. The *Medical Press and Circular*, commenting upon the matter, says: "The prospect thus opened up of wholesale and unsuspected poisoning is simply appalling. Phosphate of soda, as most persons know, is a mild aperient extensively used among babies and children. The effect of arsenic would be to produce cramps, vomiting, purging, watery and choleraic stools—in short, symptoms like those of summer diarrhœa. It is almost certain that any death so caused, in the absence of any symptoms pointing to arsenical poisoning, would be referred by the medical attendant to the disease mentioned. It is therefore not improbable that during the past few months many deaths of children have been improperly ascribed to diarrhœa, whereas their true nature was acute arsenical poisoning."

DILATATION OF THE CERVIX BY MEANS OF A MODIFIED CHAMPETIER DE RIBES BALLOON.[1]

BY JAMES D. VOORHEES, A.M., M.D.,

ASSISTANT ATTENDING PHYSICIAN TO THE SLOANE MATERNITY HOSPITAL, AND TUTOR IN OBSTETRICS AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK CITY.

THE normal mechanism of dilatation of the cervix means the manner in which the os uteri enlarges, when the waters are abundant and the membranes intact. The initial stages are in reality to be referred to the fact that the lower uterine segment possesses less muscular strength than the upper part of the uterus, and to the character of the uterine contractions; this lower segment therefore tends to expand during contraction from the action of the general intra-uterine fluid-pressure. Besides this, the longitudinal fibres of the uterus open up the os, and lastly, by separation and descent of the membranes a fluid wedge bulges through the cervix and enables the intra-uterine fluid-pressure to take direct effect upon its margins. As this process continues the internal os becomes effaced, the cervix is shortened, and finally the external os is in direct contact with the membranes and stands the pulling of the longitudinal fibres. The membranes bulge more and more, the force is greater and greater with the convexity, and finally the cervix has totally disappeared.

When the waters partially escape from a high-up rupture of the membranes, the presenting part, *i.e.*, the head, descends against the cervix and acts as a ball-valve. In such cases the process is slow, unless the os has so far dilated as to admit nearly the greatest circumference of the head, when it dips through as a wedge, and then the dilatation is rapid.

When all the waters escape, then the head must dilate the os by contact, assisted by the uterine longitudinal fibres. Now all such dry labors are not long, protracted labors. If the pains are strong, the pelvis is normal, the occiput anterior, or the child small, but especially if the cervix is soft, such labors are often the shortest.

One of the greatest bugbears for the obstetrician is the care of a case in which such happy conditions do not exist. In some cases the membranes rupture, the waters drain away, and the pains do not start. The child is compressed, the cervix is tough, oxytocics are useless, and we wonder how things will terminate. In others the pains start, are strong, the membranes rupture or do not, but for many reasons the labor is long and drawn out. Such protraction we expect in cases of posterior positions, small pelves, large children, twins, breech presentation, hydramnion cases, and the like. What concerns us principally is delay from the cervix, whether from spasm, because it is tough, rigid, and immature, or in consequence of congenital and pathological changes. Nature takes care of some of these cases; with strong pains, the spasm is relaxed, or the cervix lacerates and labor terminates. In the others there is no progress. These cases, if not helped in some way, soon show bad symptoms. The women are tired out and the bodily vigor is gone. The pulse runs up as well as the temperature. The tongue is dry, the teeth are covered by sordes; the vagina is dry; the uterus is not contracting or is approaching a tonic spasm. These conditions must be prevented. For such a state of the cervix many measures have been recommended—for weak pains, oxytocics; for spasm of the cervix, locally hot douches, cocaine and belladonna, also opium and chloral. Cases are reported to have been benefited by all of these measures. Undoubtedly chloral by the rectum is the best remedy. It gives sleep and rest, and restores the nervous tone. It does not diminish the force or frequency of the uterine contractions, and relaxes any spasm of the cervix. Often labor terminates quickly after its use.

For true rigidity the above treatment fails and something mechanical is necessary. Tents have been recommended and used. They are now obsolete. Their action is slow, painful, and uncertain. The danger of infection is very great.

Manual dilatation of the cervix has a wide field and is the only method used by many men. We always have our hands with us, which is a very important fact. The method is painful and demands anæsthesia. In cases of emergency, severe hemorrhage, placenta prævia, eclampsia, prolapse of the cord, etc., other procedures are too slow. Dilatation is readily accomplished in cases of soft cervix before a resort to forceps or version. Yet nature acts differently ordinarily. When the hand is used the cervix most often yields only by tearing.

Incision of the cervix is rarely necessary. It is demanded only in cases of cicatricial and organic changes in the cervix, and when, in dilating, a tear has started on one side of the os. Dührssen's incisions made at other points make smaller rents—not a deep one which will endanger the lower uterine zone.

The natural dilator of the cervix is a fluid wedge. If we can imitate it we respect all the physiological requirements, we help nature after her own dictates, and exactly to the measure of her needs. We use no violence, and such a measure ought to be very effective.

Dr. Robert Barnes thought by his fiddle-shaped rubber bags to have solved the difficulty. They have been in use since 1860. They are certainly of advantage in many cases, but their field of usefulness is limited. They expand the cervix in some cases; gripped in the os, they exert an eccentric force which might wear out a muscular resistance. They often start pains and accelerate labor, acting as an intra-uterine irritant, a foreign body. They will induce labor, but not surely. They will soften a cervix, preliminary to a resort to the forceps or version, but not regularly. They might stop a hemorrhage in placenta prævia, but not certainly. They are not used extensively, therefore, and why? (1) It is difficult to introduce them into a cervix admitting less than two fingers; there is so much bulk. (2) Their shape is incorrect. It is of a sort one often sees in a breech or shoulder presentation—an hourglass constriction—

[1] Awarded the Stevens Triennial Prize by Columbia University, June 13, 1900.

which does not dilate the cervix. They slip either into the uterus or vagina without accomplishing anything. (3) The material is wrong. Nature's bag is inelastic. They are very distensible. In filling them one cannot regulate the pressure. The dilatation may be too forcible, consequently they burst. They soon

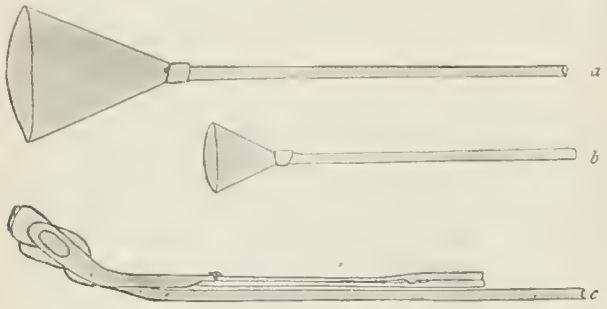

FIG. 1.—*a*, Largest bag; *b*, smallest bag; one-quarter actual size; *c*, bag rolled up in the introducing-forceps.

crack and rot, and therefore are often useless in an emergency. (4) They are not reliable in induction of labor. (5) They are too slow a dilator in eclampsia. (6) In placenta prævia they do not surely stop the hemorrhage.

Champetier de Ribes in his early experience used a rubber bag of Tarnier, a small ampulla attached to a tube. He found that this rubber bag did well as a cervical dilator in some cases, but not in all. He therefore determined to make a better one. It was to be longer, conical, impermeable, and inexpansible beyond a certain volume. It was to be strong to resist uterine and abdominal contraction, and long enough to fill the cervix. He devised a long conical balloon with a slight constriction forming a neck. To it was attached a tube in which was a stop-cock. To be inexpansible it was made of fine silk, and to be impermeable it was covered with thin rubber.

Champetier's balloon has been quite extensively used in Europe, but not very much, so far as I can learn, in this country. Pinard has used it in forty cases to induce labor, with most rapid results. In twenty-three, labor was completed in six to twelve hours; in seven, in seventeen to twenty-four hours; and in ten, in twenty-four to forty-eight hours. Herman and Spencer have also used it successfully to induce labor. G. F. Blacker[1] reports twenty-two cases in which the balloon has been used in placenta prævia with good results. Of these one mother died, and she of sepsis, which had been manifest at the beginning of the labor; of the children fourteen were alive; of the still-births, six were premature. In all

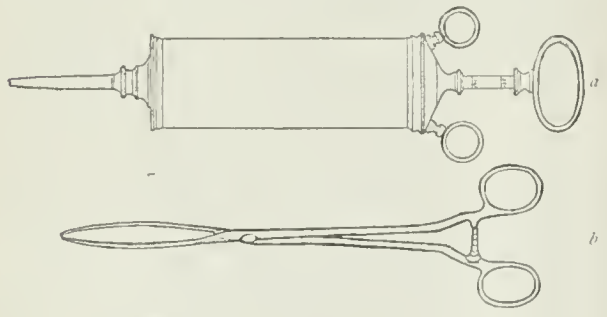

FIG. 2.—*a*, Syringe; *b*, forceps; one-quarter actual size.

cases hemorrhage was controlled by traction on the balloon.

All of the above men used Champetier's large balloon. Lately he has made them of six different sizes, ranging from a cone whose base is 3 cm. in diameter to one whose base is 8 cm. in diameter. These are more generally convenient and easier of introduction when the os is small.

In the fall of 1897 Dr. James W. McLane, the attending physician to the Sloane Maternity Hospital, began to use Champetier's balloons. At once we found that they were not so strong and durable as they were supposed to be. They would hold only so much fluid and no more. If the tension was too great, they would burst in the seams. They would stand but little traction on the tube. So having only one set, my supply soon gave out.

The balloons were expensive—$1.50 singly and $9 the set. As Colin's in Paris was the only place where they could be bought, it took a long time to get them. To make them more available and to remedy their faults, I suggested to a rubber manufacturing company of New York to make one for trial. It was to be made of thin canvas and covered by a thicker rubber. This was done and a sample sent. It proved very satisfactory. This original one is now intact after a number of trials and two years of service. A set of four was then made. Not one of them has burst. They are inexpensive—only $1 a set.

Description of the Balloon and Forceps.—(1) The balloon is conical in shape. For best results it must be impervious and inexpansible. It must be strong enough to resist uterine and abdominal contraction, also to stand traction on the tube. It is therefore made of thin canvas, firmly sewed, and covered by a rather thick rubber, carefully cemented. Everything must be of such material as can be readily boiled and then kept for a short time in some antiseptic solution; also a material which will stand the action of the liquor amnii and vaginal mucus.

There are four sizes: No. 1, diameter of base of cone, 3 cm.; capacity, 10 c.c. No. 2, diameter of base of cone, 5 cm.; capacity, 50 c.c. No. 3, diameter of base of cone, 6 cm.; capacity, 100 c.c. No. 4, diameter of base of cone, 8 cm.; capacity, 200 c.c. No. 1 dilates, therefore, to two fingers plus; No. 2 to three fingers; No. 3 to four fingers; No. 4 to four fingers plus—almost five fingers. The size used at first depends on the size of the os. The balloons are best kept in talcum or lycopodium.

(2) The Forceps (see Fig. 1, *c*; Fig. 2, *b*): This instrument is not absolutely necessary. Any dressing-forceps or sponge-holder will do, or one can use the fingers alone. The most convenient one is a forceps with a clamp. It should have a slight pelvic curve; the blades should diverge and meet again at the tips. The blades should be smooth—no serrations—so as not to bring out the bag on removal of the forceps. A small fenestra in the blades holds the bag firmly in its grasp. The length is 25 cm.

The Operation.—(1) The instruments necessary are: set of balloons, introducing-forceps, tape, scissors, and syringe.

(2) Solutions: Some antiseptic solution in case the bag ruptures, *e.g.*, lysol (one-half per cent.), carbolic acid two per cent., bichloride of mercury 1:5,000.

(3) Assistants: One to inject, the operator holding the bag in position; another to give chloroform. An anæsthetic is not necessary but makes the introduction easier. If the woman is brought down to the edge of the bed two assistants are necessary for the extremities. Yet you can get along with only one.

(4) Preparation of the instrument, patient, and operator: (*a*) The balloon, forceps, scissors, tape, and syringe are boiled for five minutes and then kept in carbolic-acid solution five per cent., or in lysol solution one-half per cent. (*b*) The patient is prepared as for induction of labor or for delivery. She is given a cleansing bath and an enema. The vulva, groin, and thighs are scrubbed carefully with green soap, and

[1] Transactions of the Obstetrical Society, London, 1898, vol. xxxix.

then irrigated, first with alcohol and after with bichloride solution 1:5,000. A sterile pad is put on the vulva and kept there until time of introduction. The woman has on sterile leggings. She is brought to the edge of the bed or table. Under her buttocks is a perineal or Kelly pad, covered by a sterile towel, and a sterile towel is placed over her abdomen. Assistants may hold the extremities. She voids her urine or is catheterized. The vagina is thoroughly irrigated and cleansed by a lysol one-half-per-cent. douche. Some cases need an anæsthetic. If a preliminary dilatation by means of a divulsor is necessary, if the cervix is high up, if the patient is nervous or is a primipara with a small vulvar orifice, light chloroform narcosis can be induced.

(5) The operator: His hands and forearms are thoroughly sterilized. He has on a sterile gown.

Method of introduction: If the cervix is undilated, a Goodell dilator or the finger must be forced through as a preliminary measure. Then, if the membranes are unruptured, they are to be separated as much as possible about the os. Remove all the air from the syringe and fill it with the antiseptic fluid. Fill the bag first to see that it is intact. The balloon to be used depends upon the size of the os. Remove all air and solution from the bag. Tuck in its base, roll it up, and clamp it tightly in the forceps (see Fig. 1, *c*). Then dip it in lysol. Two fingers of the left hand are now carried into the vagina as far as the os. On them the bag in the forceps is guided into the opening. With the base well inside the forceps is unclamped and removed. The bag is then held in place by the fingers while an assistant, or the operator with the other hand, slowly and gradually fills it with fluid. The amount necessary is determined by the resistance or by feeling the tension of the bag. The tube is securely tied by the tape and then put into the vagina. A sterile pad is now put over the vulva. The bag cannot get out until the cervix has dilated to admit its base. If the pains are weak and infrequent or the dilatation is slow, from time to time traction can be made on the tube until the balloon comes through. Then if things are not progressing, if the cervix is unsoftened and the pains are weak, a larger balloon can be inserted. No balloon should be left in longer than eighteen to twenty-four hours, as the danger of infection is great. When a bag comes out an examination should be made to see that the cord has not come down.

Results.—I publish all cases in which the balloons have been employed. These, seventy-two in number, are not selected. They are those in which the indication was certain, and, in almost all, other methods had been tried and failed. All were not successful, but certain advantages were obtained and the field of usefulness of the bags was more definitely determined. The cases are taken from 2,113 during the past two years to September 1, 1899, in the writer's experience at the Sloane Maternity Hospital. I did not insert all the balloons myself. Some were introduced by my assistants, who have kept exact records.

1. Dry Labors: (*a*) Vertex cases; no pains. During this time there were three hundred and fifty dry labors, but the bags have been used in only twenty-seven. There were eleven primiparæ and sixteen multiparæ; three had justo-minor pelves; one a flat pelvis with an internal conjugate diameter of 8.25 cm.; the other pelves were normal. In four the position was posterior; the head was engaged in six; in twenty-one it was above the brim. In nineteen oxytocics, quinine and strychnine, had been given without starting the pains. The time from rupture of the membranes until the introduction of the bag varied from three to forty-eight hours; the average time, eighteen hours one minute. In nineteen cases the cervix was tough. In one case three bags were used; in three, two bags were used; in twenty-three, only one.

Pains started earliest—immediately; latest, after sixteen hours thirty minutes; average, one hour one minute. The bag was in the cervix—longest, thirteen hours fifty-five minutes; shortest, one hour five minutes; average, four hours fifty-three minutes. In twenty-two cases pains were strong, and in five they were weak. The cervix admitted three fingers when the bag came out, seven times; four fingers, fourteen times; five fingers twice; it was fully dilated four times.

After the balloon came out, the cervix was found to be soft in twenty-five cases. The longest time till complete dilatation after the introduction of the bag was fifteen hours thirty-eight minutes: shortest, one hour forty minutes; there were only five cases over ten hours; average, five hours forty minutes.

The child was in bad condition three times when the bag was put in; six children were asphyxiated at birth, three slightly, two moderately, one deeply. One child was still-born; the cord had prolapsed, and through carelessness it was detected too late. There was no sepsis. Four patients had temperatures from 100° to 100.8° F.

All births were spontaneous but three; one was a case of high-forceps operation in the flat pelvis; one of a medium forceps; and the other of a low forceps. The last was done to deliver quickly in the case in which the cord prolapsed.

(*b*) Breech cases: During the two years there were one hundred and two breech cases, and the bag was used in only six. Two were primiparæ and four multiparæ. One had a flat pelvis with previous difficult births. Two were over time and had large children. In two, pains had started but were weak. In one the membranes had ruptured thirty hours before the bag was put in. In two, pains started immediately, and in two after thirty and forty-five minutes respectively. In one the umbilical souffle was present; and in four the fœtal heart was slow and irregular. Bags were in the cervix from five minutes to two hours forty minutes. Shortest time from introduction of the bag until complete dilatation, one hour twenty minutes; longest, six hours thirty minutes. Four children were delivered spontaneously, two by extraction; four children were born asphyxiated, three moderately. There were no cases of high temperature in the puerperium. The cervix was only slightly torn in all cases.

2. Protracted Labors: In the two years at the hospital there were fifty-six protracted labors. The balloon was used in twenty-two. Ten were primiparæ and twelve were multiparæ. There were ten posterior positions. In only three cases was the head engaged at the beginning of labor. Two patients had flat pelves, and two justo-minor. In fifteen the pains were weak. In all oxytocics had been used; in twelve, chloral. In three there was some manual dilatation. In all, the membranes had been ruptured before the bags were introduced. The shortest time of pains before the bags were used was eight hours; longest, forty-eight hours; average, twenty-three hours thirty-nine minutes. The cervix admitted one finger plus in two cases; two fingers in nine; and three fingers in eleven, at time of introduction. The cervix was tough in all but one; in one it was cicatricial, and in another cartilaginous. One bag was used in fifteen cases; two bags in seven cases. The shortest time of bags in the cervix was one minute; longest time seven hours thirty minutes; average, two hours fifty-five minutes. Dilatation when the bags came out—cervix admitted three fingers, three times; four fingers, eleven times; five fingers, eleven times. Shortest time from introduction of the balloon till complete dilatation was thirty minutes; longest, twenty-

three hours thirty-five minutes; average, six hours thirty-six minutes; one never fully dilated (cartilaginous).

The condition of the child when the bag was introduced was good in fourteen cases. There was an umbilical souffle in one; in three the fœtal heart was slow and irregular; in one the child was passing meconium.

Twelve cases terminated spontaneously; two by high forceps (one after replacement of the cord and the other after a symphyseotomy); four by a medium forceps; two by a low forceps; one by a version and craniotomy.

Only one child was still-born. This one had its after-coming head perforated, as a cartilaginous cervix held it, and the child died. Ten children were not at all asphyxiated at birth, four slightly so, four moderately, four deeply; but in all cases they recovered and survived.

Five women had fever; one had a temperature of 100° F. on the third day, due to the breasts; one 101° F., reactionary after symphyseotomy; one 101° F., reactionary after a severe hemorrhage; another 101–103° F. for seven days, due to a cystitis and ureteritis; and one died of a virulent sepsis on the sixth day. She was anæmic, underfed, and had attempted abortion. She had a long, dry labor, with many examinations. Her placenta was retained and she had an extensive tear. Autopsy showed a suppurative metritis, chronic nephritis, and miliary tuberculosis.

3. Induction of Labor: In the 2,113 cases, labor was induced fifty-five times, a bougie being the method usually adopted. During this time there had been twenty-six cases of eclampsia—accouchement forcé being the usual method of treatment. In inducing labor, the bag was used alone in eight cases, in one after rupturing the membranes, and in seven after the bougie had practically failed. Seven patients were primiparæ and nine multiparæ.

The indication for five was a contracted pelvis; three were cases of eclampsia; two had albuminuria; two were cases of chronic endocarditis; one had a large ovarian cyst, one severe asthma and emphysema, one accidental hemorrhage, and one was a woman who had the history of two previous still-births. Four were occipito-posterior positions, two breech presentations, one twins. The membranes had ruptured in seven—the shortest time twenty minutes, and the longest fourteen hours fifty-seven minutes. All the children were premature, seven and three-fourths to eight and three-fourths months. Pains had started slightly in two; no pains in fourteen; in seven a bougie had been in the uterus from five hours nineteen minutes to twenty-seven hours. All the cervices were tough, five immature and long. The cervix was closed in one, admitted one finger in ten cases, two fingers in five cases. One bag was used in four cases, two in ten cases, three in four cases. The shortest time a bag was in the cervix was one hour fifteen minutes; longest, thirteen hours thirty-five minutes; average, ten hours fifteen minutes. Pains started—shortest time, immediately; longest time, three hours thirty minutes; average, two hours twenty-seven minutes. There were no pains in one case, terminated by accouchement forcé in a bad case of eclampsia. The time from introduction till complete dilatation was, shortest, two hours one minute; longest, twenty-nine hours thirty-one minutes; average, fourteen hours two minutes.

Nine patients were delivered spontaneously; two breech cases by extraction; one by version; two by forceps; one by basiotripsy, as the forceps failed and the child died; and one by a perforation of the after-coming head after the child had died. Nine children were not asphyxiated at birth, two were moderately so, and three deeply. Three were still-born—two were perforated in cases of eclampsia as above, and the third was the second child of twins.

Four women had fever. One had 102° F. on fourth day, the cause of which is unknown. The other three died; two were cases of eclampsia, and the third a case of acute yellow atrophy of the liver.

4. Placenta Prævia: In the two years there were fourteen cases of placenta prævia, but the balloons were used in only three. All were of multiparæ. One patient had had three hemorrhages before admission; she was very anæmic, pulse slow but small. Another had been bleeding continuously for four days; she was anæmic, but pulse was good. The third had had three hemorrhages, but her condition was good. The first was almost at term; the second, seven and one-half months along; the third, seven and one-fourth months. The presentations were L.O.P., L.D.A., and R.O., respectively. No pains had started. The cervix was firm in one, tough in the other two. The cervix admitted one finger in all; the membranes were intact. Pains started almost immediately in the first, in twelve minutes in the second, and in seven minutes in the third—after the introduction of the bags. Nos. 2, 3, and 4 were used in the first case; they were in the cervix thirty-one minutes. The patient lost twenty ounces of blood between the introductions. In the second, Nos. 2 and 3 were used. They were in the cervix three hours forty minutes. Two ounces of blood were lost between the introductions. In the third, Nos. 2 and 4 were used. They were in the cervix three hours seventeen minutes. Two ounces of blood were lost between introductions. There was no hemorrhage while the balloons were in. Tractions on the tube were used in all. All the patients were finally delivered by version and extraction. All had pulses below 100 after delivery. The children of the second and third were deeply asphyxiated. The first came around all right, but the other was very premature, weighing three pounds thirteen ounces, and lived only seven hours. The child of the other was still-born. The cervix gripped the neck and delayed the delivery enough to kill it.

The first patient had a fever of 101° F. on the fourth day—a mild absorption; the second, 101° F. on the first day—reactionary; the third, no elevation of temperature.

Action of the Balloon.—With the membranes intact, the distention of the balloon shoves them up and separates them below near the internal os. The cone shape keeps the bag in the uterus. The apex fills the cervix. It cannot get out. With the membranes ruptured, the balloon plugs the cervix, taking the place of the natural bag. The rest of the liquor amnii cannot escape; it therefore protects the child, and so is especially advantageous in breech cases. The bag is a foreign body in the uterus, therefore an irritant to uterine contractions. It pushes up the head or presenting part, increasing the intra-uterine pressure. In this way it stimulates the uterus to contract. The weight of the child drives the balloon down into the cervix, causing an eccentric pressure and so dilating the cervix. Again, there is nothing like a body in the cervix to start labor pains reflexly.

If no contractions begin, traction on the tube may start them and at the same time dilate the cervix. If the uterus contracts, the cone is driven down and opens the os. If the cervix is in spasm, the constant pressure of the bag will tire the muscle and it will relax. While in the uterus, it also causes a physiological softening. If the cervix is long, the internal os is first acted upon.

In some cases the pains start immediately, ordinarily in three or four hours. They may be weak and infrequent at first, and later strong; or they may be strong and frequent from the beginning. Often when

successive balloons are used, in the interim the pains cease, but start up again as soon as the next size of the balloon is introduced. Whether the pains start soon or late, or are strong or weak, generally depends on the time of pregnancy, the condition of the os, or the duration of labor. With the contractions of the uterus and dilatation of the cervix, the bag descends and passes through the os into the vagina. Sometimes the bag remains there. It will do so unless the vagina expels it, or the head, in its advance, drives it out of the vulva. After balloon No. 4 comes through the cervix, unless the brim resists, the head dips into it and completes the dilatation. The labors then generally terminate spontaneously. In this way the cervix is gradually opened without violence, and no deep lacerations, which later bother the patient, result. Quite different is a cervix after a manual dilatation.

In dry labors, the balloons surely start pains when oxytocics fail. They dilate the cervix rapidly and diminish fœtal mortality. This is very remarkable in breech cases. In them you do not have to pull down a foot so early, and thereby save the child from prolonged pressure. The bag also prepares the cervix for the after-coming head.

In protracted labors the birth is hastened, saving the mother untold suffering. The balloons dilate the cervix when other measures fail, and many labors terminate spontaneously which otherwise would require manual dilatation, with laceration of the cervix, and instrumental aid. However, if forceps or version is necessary, the cervix is softer and the os is wider and so in better shape for these operations.

The balloons certainly start labor, even when a bougie has failed. They are especially advantageous in those cases in which the membranes have ruptured early.

In cases of contracted pelvis, ordinarily the dilatation is slow. The bag makes it more rapid, allows the head to engage, and sooner prepares the case for major operations if they are necessary.

In albuminuria and eclampsia, the uterus is not very irritable, so that dilatation is slow. Often no pains start at all, and the only advance we can get is by traction on the tube.

In placenta prævia the balloons can be used with the membranes intact or ruptured. If they are intact, they perhaps separate the placenta a little more, but as few attachments are directly central, this makes little difference. The bag is an excellent tampon and will stop all active bleeding. It presses directly against the bleeding sinuses. Again, if the membranes are intact, a subsequent version is more easily accomplished. With the membranes ruptured, the bag is in the amniotic cavity and presses the separated portion of the placenta against the uterine wall. If the bag itself does not stop the hemorrhage a little traction on the tube will always do it. By starting uterine contractions, by softening and dilating the cervix, the bag accomplishes much in placenta prævia.

Also by not being required to use the child's foot to do this we diminish fœtal mortality; besides, the bag is a much better plug for the cervix than the half-breech. Then, with the cervix so prepared, the ease of delivery after the expulsion of the largest bag is remarkable—quite different from a delivery through a tough cervix after a Braxton-Hicks version.

Advantages of the Modified Champetier de Ribes Balloons over Others, i.e., Barnes' Bags.—(1) They are easier to introduce, less bulky. (2) The shape is more like that of nature's bag. (3) They are inexpansible and cannot burst. (4) They cannot get out through the cervix without dilating it. (5) They are more reliable in starting labor pains. (6) They keep in the liquor amnii. (7) They do not rot. (8) They surely stop hemorrhage in placenta prævia. (9) One can pull on the tube. (10) They are less apt to displace the presenting part.

Objections to the Balloons.—(1) They may rupture the membranes. This happens rarely, and it makes little difference if they do. The fœtus suffers some, but little, as the waters cannot all drain away. If the fluid does escape, the dilatation is rapid enough to do little harm.

(2) They may separate the placenta—only in placenta prævia. But the bag either arrests the hemorrhage on being filled or when traction is made on the tube.

(3) They may increase the tension in the interior of the uterus. It is not great and no harm is ever done. It is not painful to the patient and never ruptures or weakens the uterus.

(4) They may displace the presenting part. This is possible, but by slow distention of the bag and by watching the presenting part during the distention, we can keep it in place. This accident occurred only once in the seventy-two cases. It was in a contracted pelvis, and perhaps would have occurred spontaneously. If it does occur, it can be easily rectified, for the conditions are very favorable for a version.

(5) The cord may prolapse. For this accident to occur, the cord must be long or about the neck. It happened twice in my cases. In one it was immediately replaced, forceps applied, and a living child delivered. In the other, the condition was not discovered until too late—the caput was in sight with the cord. The bag had been out three hours. Although the forceps was applied and the child quickly delivered, it was still-born.

Rule: Always examine when the balloon comes through the cervix.

(6) Sepsis. Balloons can be boiled. If the aseptic technique is correct there should be no infection. In my cases ten patients had high temperatures; one had a mild sapræmia; one died of a virulent sepsis. She was probably infected before treatment. She had many other causes than the bag for infection.

Indications.—(1) To start pains, when the membranes have been long ruptured, especially in breech cases; (2) in dry labors when the child is in bad condition—there is an umbilical souffle, or it is passing meconium, or the heart is slow or irregular; (3) in prolonged and protracted labors, oxytocics and chloral failing; (4) in rigid cervices of all kinds; (5) in hydramnion, when it is necessary to rupture the membranes; (6) in cases of twins, when it is necessary to rupture the membranes; (7) in shoulder presentations, when a Braxton-Hicks version cannot be easily done; (8) to induce labor: (*a*) In cases in which a bougie fails or when the membranes are ruptured in its introduction; (*b*) in albuminuria; (*c*) in contracted pelves—to let the head down against the brim to engage; or preparatory to forceps or version; (*d*) in case of a dead fœtus; (*e*) in chronic endocarditis; (9) in placenta prævia, especially those cases in which the cervix is tough, or in which the placenta is over the os and one cannot turn easily, preparatory to version.

Conclusions.—1. Dilatation of the cervix is readily accomplished by a hydrostatic bag.

2. The best balloon for it is the modified Champetier de Ribes—it being inexpansible, impermeable, strong, and inexpensive.

3. The Barnes bag is unsatisfactory.

4. The operation is easy and not dangerous.

5. The dilatation is rapid.

6. The uterine contractions always start after its introduction into the uterus.

7. Labor is hastened, and almost always terminates spontaneously after expulsion of the balloon, or the easy extraction of the child is possible.

8. The balloons control hemorrhage in placenta prævia, and diminish fœtal mortality.

9. The balloons meet all the indications before mentioned.

OBSERVATIONS ON THE GASTRIC FUNCTIONS BEFORE AND AFTER GASTRO-ENTEROSTOMY.*

BY CHARLES S. FISHER, PH.D., M.D.,

NEW YORK.

THE cases presented in this paper are representative of certain benign chronic diseases of the stomach for the relief of which the operation of gastro-enterostomy has frequently been resorted to in the past few years. The results obtained by this operation in such cases have formed the basis for much discussion and many statistics.

The following cases are few in number, but they have the advantage of having been carefully studied for periods of months and years previous to operation and for the same length of time afterward. It has been possible to note the very gradual changes which took place in the motor and secretory functions of the stomach before operation, and to observe the effect of operation upon these functions. The apparent tediousness attendant upon the presentation of so many analyses is counterbalanced by the necessity of their presence in order to explain the causes which led to operation and the results obtained by the same. All the ordinary symptomatology has been eliminated in these cases, for as clinical types they are well known. These observations are directed entirely to the functions of the stomach and its size and position before and after operation. The surgical side of these cases has already been presented by Dr. Robert F. Weir,[1] by whom all the operations were performed.

CASE I.—Benign pyloric stenosis with dilatation, peripyloritis, posterior gastro-enterostomy. A. P——, cigarmaker, aged forty-one years, came under observation in December, 1895. His principal symptom at that time was pain of such an intense, spasmodic, and remittent character as to simulate hepatic colic at times. At other times it resembled a crise gastrique. It occurred independently of all food taken, and seemed to be more or less dependent upon those movements which brought into play the abdominal muscles. The patient suffered from no gastric symptoms and had been perfectly well previously. He was well nourished, gave no specific history, no objective or subjective symptoms of gall stones, but had suffered from an attack of peritonitis some years before. He had been troubled with constipation for one year. Several analyses of gastric contents and physical examinations were made with the following results:

December, 1895: Trial breakfast; one hour's digestion. The gastric contents were normal in appearance and character; free hydrochloric acid, 0.7–1.0 per 1,000; total acidity, 40–60; organic acid, traces; albumen and starch digestion, normal. Repeated examinations on an empty stomach revealed the size, location, and motility of the organ as normal. The greater curvature did not reach the umbilicus.

The patient was kept under observation for a time, but finally disappeared until October, 1897. He had been treated for hepatic colic in the mean time without benefit. His pain had increased in intensity and frequency, and in addition he was suffering from most pronounced dyspeptic symptoms. The following results were obtained by repeated examination:

October, 1897: Trial breakfast; one hour's digestion. The gastric contents large in quantity, fermenting and rancid; free hydrochloric acid, 1.5 per 1,000; total acidity, 120–140; organic acids in quantity; peptic ferments normal; yeast and sarcinæ in abundance. Physical examinations by lavage many hours after meals always revealed large quantities of fermenting food residue, and the greater curvature was located two inches below the umbilicus.

This condition of pyloric stenosis, hyperacidity, and dilatation existed practically at the time of operation, March 26, 1898. The patient made a good recovery and has been free from pain ever since. He has had no treatment beyond dietetic precautions. On February 27, 1900, I began the following series of examinations:

February 27, 1900: Trial breakfast; one hour's digestion. Gastric contents normal in appearance and consistency, but containing considerable bile; free hydrochloric acid, 2 per 1,000; total acidity, 86; organic acids in small quantities; albumen digestion, 81 per cent.; starch digestion delayed; no yeast or sarcinæ.

February 28th: Riegel meal; two and one-half hours' digestion. Gastric contents normal in consistency, green color; free hydrochloric acid 0.5 per 1,000, combined hydrochloric acid 1.6 per 1,000, total hydrochloric acid 2.1 per 1,000; total acidity, 92; organic acids, 32; albumen digestion, 79 per cent.; starch digestion normal; no yeast, etc.

March 5th: Trial breakfast; one hour. Gastric contents of normal character but green; free hydrochloric acid, 1.8 per 1,000; total acidity, 84.

* Read before the American Surgical Association, May 2, 1900, at Washington, D. C.

March 6th: Riegel meal; three and one-half hours' digestion. Gastric contents green and well digested; free hydrochloric acid, 1.4 per 1,000; total acidity, 92, organic acids, traces; albumen digestion normal.

March 9th: Physical examination. Leube's meal; seven hours. The stomach contains no food residue, but 50 c.c. of a green, acid fluid; free hydrochloric acid, 1.3 per 1,000; total acidity, 96. The greater curvature was located at the umbilicus.

From the results obtained by these analyses it appears that the hyperacidity existing at the time of operation has not disappeared at the end of two years. The free hydrochloric acid after trial breakfasts ranges from 1.8 to 2 per 1,000, with a fairly constant total acidity (86–96). The free hydrochloric acid for Riegel meals is somewhat lower (0.5–1.4 per 1,000), whereas the total acidity remains stationary (96). Bile is constantly present. The motor functions have become normal, and the dilatation has been reduced.

Case II.—Benign pyloric stenosis, hypertrophic; gastro-enterostomy and entero-anastomosis by Gallet's method. In this patient, I. W——, tailor, aged thirty-five years, all the symptoms of pyloric stenosis were present from the beginning. Very active symptoms had been noticed for nine months, but a weak stomach had existed for years. There was no indication in the history of a tumor. The following examinations were made:

November 7, 1898: Trial breakfast; one hour. Gastric contents extremely rancid; free hydrochloric acid, 0.8 per 1,000; total acidity, 79; organic acids, fair; yeast and sarcinæ abundant.

November 9th: Trial breakfast; one hour. Same general character as before; free hydrochloric acid, 1.2 per 1,000; total acidity, 90; organic acids, marked.

November 14th: Trial breakfast, one hour. Same as before. Free hydrochloric acid, 1.7 per 1,000; total acidity, 100; organic acids in quantity; albumen and starch digestion normal; yeast and sarcinæ in abundance.

December 9th: Trial breakfast. Free hydrochloric acid, 1.8 per 1,000; total acidity, 140; marked fermentation and organic acids in abundance.

November 9th and 18th: Physical examinations reveal a constant large food residue many hours after meals. The greater curvature was located two and one-half to three inches below the umbilicus.

Further examinations made at the time of operation, December 15, 1898, showed the free hydrochloric acid to have reached 2 per 1,000, with a corresponding increase in the severity of the symptoms. Diagnosis was confirmed by the operation, and the patient made a good recovery. He has been free from pain and dyspeptic symptoms ever since. The general nutrition has improved and he has been able to work. In February, 1900, fourteen months after operation, the following examinations were made:

February 28, 1900: Trial breakfast, one hour. Gastric contents were rancid and in considerable quantity; free hydrochloric acid, 1.3 per 1,000; combined hydrochloric acid, 1.9 per 1,000 (free and combined hydrochloric acid, 3.2 per 1,000); total acidity, 120; organic acids, 30; albumen digestion complete; starch digestion retarded; yeast and sarcinæ in quantity.

March 3d: Riegel meal; three hours. Gastric contents rancid; free hydrochloric acid, 1.5 per 1,000; total acidity, 120; organic acids, fair quantity; albumen digestion, 73 per cent.; yeast and sarcinæ.

March 5th: Trial breakfast; one hour. Gastric contents same as before; free hydrochloric acid, 1.6 per 1,000; total acidity, 115; organic acids abundant.

March 7th: Physical examination revealed the motility of the stomach impaired. Quantities of food were found when the organ should have been empty The greater curvature was located at the umbilicus.

It appears that the secretions, which at the time of operation were in a condition of progressive hyperacidity, are still hyperacid, fourteen months afterward, free and combined hydrochloric acid is present to the extent of 3.2 per 1,00, and the total acidity reaches 120 for both trial breakfast and Riegel meal. The motility of the stomach is still impaired, but its size has been reduced markedly.

Case III.—Hyperacidity, pyloric spasm, moderate dilatation, gastro-enterostomy with entero-anastomosis; Braun's method with Gallet's modification. J. F. S——, salesman, aged forty-four years, came under my observation in April, 1899. He gave a history of functional hyperacidity of a remittent type of two years' duration. Recently his symptoms had become more or less constant. The following are some of the examinations made at intervals from May 1 to December 19, 1899:

May 1, 1899: Trial breakfast; one hour. Gastric contents normal in appearance and consistency; free hydrochloric acid, 2.3 per 1,000; total acidity, 88; organic acids, small quantity; yeast, small quantity.

May 3d: Physical examination reveals normal size, location, and motility of the stomach.

May 8th: Trial breakfast. General appearance of contents same as before; free hydrochloric acid, 2.4 per 1,000; total acidity, 96; organic acids, negative; some yeast.

May 29th: Trial breakfast. Gastric contents show evidence of fermentation; free hydrochloric acid, 2 per 1,000; total acidity, 86; organic acids, fair; yeast in fair quantity.

August 2d: Trial breakfast. Gastric contents rancid; free hydrochloric acid, 2.1 per 1,000; total acidity, 120.

October 2d: Trial breakfast. Gastric contents very rancid; free hydrochloric acid, 2.6 per 1,000; total acidity, 104; organic acids abundant; yeast abundant; fat crystals.

October 11th: Physical examination reveals impaired motility and some dilatation.

November 29th: Trial breakfast. Very rancid contents. Free hydrochloric acid, 2.3 per 1,000; total acidity, 112.

These were the conditions at the time of operation, December 19, 1899. The hyperacidity had been constant and pyloric spasm had supervened, which finally resulted in relative impaired motility and slight dilatation. The patient recovered rapidly after operation and has been free from distress. On the following dates examinations have been made:

January 24, 1900: Trial breakfast; one hour. Gastric contents normal in appearance and consistency; free hydrochloric acid, 1.6 per 1,000; total acidity, 76; organic acids, small quantity; albumen digestion normal; retarded starch digestion; some yeast.

January 31st: Trial breakfast. Free hydrochloric acid, negative; total acidity, 60; organic acids negative.

March 9th: Trial breakfast. Contents normal in appearance; free hydrochloric acid, 2.9 per 1,000; total acidity, 136; organic aids, traces; albumen digestion, 82 per cent.; yeast in small quantities.

March 12th: Riegel meal; three hours. Free hydrochloric acid, 0.1 per 1,000; combined hydrochloric acid, 2.1 per 1,000 (free and combined hydrochloric acid, 2.2 per 1,000); total acidity, 108; organic acids, 44.

March 16th: Trial breakfast. Free hydrochloric acid, 1 per 1,000; combined hydrochloric acid, 1.6 per 1,000 (free and combined hydrochloric acid, 2.6 per 1,000); total acidity, 80; organic acids, 8; no yeast.

March 20th: Physical examination reveals the size and location of the stomach as normal and the motility restored.

In this case the functional hyperacidity, which was constant for months prior to operation, has resumed the remittent type with which it started. For six weeks subsequent to operation the free hydrochloric acid ranged from normal to subacidity (1.6 to negative); total acidity, 120–60. On March 9th, five weeks later, the patient was subjected to considerable mental distress due to business reverses, and upon examination at this time we find free hydrochloric acid, 2.9 per 1,000, with a total acidity of 136. A few days later, March 16th, we find that the free hydrochloric acid has again fallen to 1 per 1,000, with a total acidity of 80. There were no symptoms from this post-operative temporary hyperacidity, except the formation of some gas. There was absolutely no reappearance of the pain.

Case IV.—Dilatation of stomach without pyloric obstruction and with movable kidney; gastro-enterostomy and entero-anastomosis. Observations on the case began in October, 1895. Mrs. B——, aged forty years, had been suffering for years from what was apparently nervous dyspepsia. The following examinations were made at the time:

October 27, 1895: Trial breakfast; one hour. Gastric contents appear normal; free hydrochloric acid, trace; total acidity, 51; organic acids, trace; peptic ferments, normal.

October 29th: Trial breakfast. Same gross characteristics; free hydrochloric acid, 1.4 per 1,000; total acidity, 69; organic acids, traces; physical examinations reveal normal motility, somewhat vertical position of the stomach, with the greater curvature one inch below the umbilicus. Repeated examinations showed a constant fluctuating character in the secretions; free hydrochloric acid ranged from subacidity to slight hyperacidity, and the motility was constantly normal. One year later other examinations were made:

October 28, 1896: Trial breakfast. Fairly normal gross appearances; free hydrochloric acid, 0.2 to 1.0 per 1,000; total acidity, 50–60; organic acids, traces; small quantities of yeast. Physical examination revealed the size and position unchanged. There was, however, a beginning tendency to impaired motility.

From these and other examinations it appeared that the occasional hyperacidity had disappeared. Free hydrochloric acid ranged from subacidity to normal. The beginning impaired motility was accompanied by a corresponding increase in the fermentative organisms found. From this time on the atony was progressive, as the following examination will show:

March 15, 1897: Trial breakfast; one and three-fourths hours. Gastric contents rancid, fermenting; free hydrochloric acid, 0.7 per 1,000; total acidity, 65; organic acids, yeast, and sarcinæ in abundance. Physical examination showed increased atony and the greater curvature extending to one and three-fourths inches below the umbilicus.

February 4, 1898: Trial breakfast and physical examination. A large quantity of fermenting material was constantly present; free hydrochloric acid, 1.1 per 1,000; total acidity, 57; organic acids marked: increased atony, and the greater curvature more than two inches below umbilicus.

These conditions were progressive until the time of operation.

March 7, 1899, one year later: At this time free hydrochloric acid ranged from 0.1 to 1.1 per 1,000; total acidity, 5.5 to 6.5; peptic ferments normal; organic acids in quantity; abundance of yeast and sarcinæ; marked atony; greater curvature two and one-half inches below the umbilicus; freely movable and descended right kidney; considerable general emaciation. The patient made a good recovery, and, with the exception of occasional attacks of fermentation, has been well and has added some thirty pounds to her weight. One year later I had the opportunity to make the following examinations:

November 22, 1899: Trial breakfast. Free hydrochloric acid negative; total acidity, 30.

March 9, 1900: Trial breakfast: one hour. Gastric contents unchanged in appearance; free hydrochloric acid, negative; total acidity, 44; organic acid, traces; albumen digestion, 42 per cent.; starch digestion, normal; yeast, small quantity; marked presence of bile.

March 16th: Riegel meal; three hours. Contents of stomach slightly rancid; free hydrochloric acid, negative; combined hydrochloric acid, 0.1 per 1,000; total acidity, 26; organic acids, 21; some yeast and bile present.

March 17th to 19th: Phsyical examinations reveal some slight food residue seven hours after a meal. Upon early lavage the stomach is constantly empty. The greater curvature is located two inches below the umbilicus. The right kidney is still freely movable.

In this case, notwithstanding the very evident general improvement in the physical condition of the patient, there has been no attempt at repair on the part of the glandular structures of the stomach. On the contrary, the subacidity seems to have gone on to a fair state of achylia. The size and position of the stomach remain about the same. The motility has apparently improved to a great extent.

It would be manifestly impossible to draw very general conclusions from this limited number of cases. It can only be said of them that they represent certain distinct types for which gastro-enterostomy is performed, and that it is in a comparatively small number of cases only that patients can be controlled both before and after operation so as to render the observations conclusive. The immediate effect of gastro-enterostomy in cases of benign pyloric stenosis is relief, which relief, coming naturally as a result of the cessation of the spasm of the sphincter pylori, is apt to produce an exaggerated idea of the ultimate effect of the operation upon the various gastric functions. Hence the real value of this operation can be judged only by a careful study of those cases in which it has been possible not only to observe the functions of the stomach for a protracted period after operation, but also to have been able to follow the very gradual changes which occurred in these functions during the months which preceded the operation. On the other hand, the very relief experienced by the patient after operation is to a certain extent an obstacle to a thorough study of the changes which take place in the gastric functions, for such patients are very apt to overestimate the capabilities of their stomachs, and so deliver themselves over to dietetic excesses, which latter are well calculated not only to influence the expected repair, but in many cases to retard it. Any temporary return of dyspeptic symptoms in these cases is very likely, however, to cause the most intense depression, especially in those whose mental tone has been materially undermined by years of suffering. This mental depression is very antagonistic to the ultimate repair of the gastric function in certain cases. Hence the absolute control of the patient is most desirable.

The two functions of the stomach which are primarily involved in this discussion are the secretion of hydrochloric acid and the motility. The cause for operation in a large proportion of cases is either an abnormal increase of the one or a decided impairment of the other. Of the two functions the one which has engaged the attention of observers most is the secre-

tion of acid, and the reports and statistics of clinics have been devoted to the effect of gastro-enterostomy upon hyperchlorhydria. In this connection a closer study of the first three cases may be of interest.

In Case I. there are many reasons to believe that the cause for the obstruction was located externally to the pylorus in the beginning. Not only the history of the case, but its exceedingly slow course and the findings at the operating-table, are indicative of this. The examination of the gastric functions in December, 1895, gave nothing abnormal. The figures for free hydrochloric acid at that time showed even a tendency to subacidity (0.7–1.0 per 1,000). The other functions were found to be normal. Their conditions very gradually changed until October, 1897, when the examinations revealed a pronounced pyloric obstruction with hyperacidity (free hydrochloric acid, 1.5 per 1,000 and over; total acidity, 120–140). During all this time there never were any symptoms suggesting ulcer or tumor. Two years after operation we find the hyperacidity still present. All examinations give quantities for free hydrochloric acid ranging from 1.5 to 2.0 per 1,000, and for total acidity from 86 to 96, both for trial breakfast and Riegel meal. Only on one occasion, February 28, 1900, did the figures for free hydrochloric acid indicate subacidity (0.5 per 1,000); but the combined hydrochloric acid reached 1.6 per 1,000, and the total acidity 92. If there was any doubt on this score, it was dispelled by the finding of a small quantity of acid fluid on an empty stomach, which gave the figures 1.3 per 1,000 for free hydrochloric acid and 96 for the total acidity. The digestion of albumen was normal (79–81 per cent.).

In Case II. we have somewhat similar conditions, although here, both from the history of the case and the findings at the operating-table, a primary ulcer at the pylorus might be suspected. Actual symptoms of the same never existed, however. From the comparative progressive increase of the acidity (free hydrochloric acid, 1.2 to 2.0 per 1,000; total acidity, 92 to 130) and the severity of the symptoms of obstructions, it could be inferred that the former was due to the latter. Fourteen months after operation it is found that the change in the hyperacidity has not kept pace with the general improvement. Free hydrochloric acid is still present to the extent of 1.3 to 1.5 per 1,000, figures within the normal, perhaps, were it not that the combined hydrochloric acid reaches 1.9 per 1,000, making a total figure for hydrochloric acid of 3.2 per 1,000. The total acidity was correspondingly high (120 for trial breakfast and Riegel meal). The digestion of albumen was normal (73 to 100 per cent.).

Case III. is typical of those conditions in which the hyperacidity is primary or purely functional. The pyloric obstruction and slight dilatation were secondary in this case. Repeated examinations from May 1 to December 19, 1899, showed this plainly. With a constant hyperacidity of 2.3 per 1,000 for free hydrochloric acid, pyloric spasm and obstruction gradually supervened. The examinations after operation are interesting. The hyperacidity steadily decreased until January 31, 1900, when there existed a condition of subacidity (free hydrochloric acid, negative; total acidity, 60). Suddenly, as a result of emotional disturbances, we again find, on March 9, 1900, a most decided hyperacidity (free hydrochloric acid, 2.9 per 1,000; total acidity, 136). As the mental excitement disappeared a decline in the acidity took place, until, on March 12th, we again have normal figures (free hydrochloric acid, 0.1 per 1,000; combined hydrochloric acid, 2.1 per 1,000 after a Riegel meal), and on March 16th the corresponding figures (free hydrochloric acid, 1; combined hydrochloric acid, 1.6 per 1,000; total acidity, 80), after a trial breakfast. The acidity after operation in this case depended upon the general nervous condition of the patient and ranged from subacidity to normal, differing in this respect essentially from Cases I. and II.

The observations in Case IV., which extended over a period of four years prior to operation, made it possible to follow the very gradual changes which took place in the functions and size of the stomach. The case is further interesting in that it represents a class of chronic gastric disease, the existence of which has been denied. I refer to simple gastric dilatation as a result of atony. From the history it can be seen that in October, 1895, there existed a condition of nervous dyspepsia with varying acidity (free hydrochloric acid, traces to 1.4 per 1.000; total acidity, 51 to 68), and a tendency to gastroptosis. This state of things had existed for a long time. In 1896, one year later, during which time the patient's symptoms increased in severity, the acidity had changed to a subacid condition (free hydrochloric acid, 0.2–1.0 per 1,000), at the same time that atony of the muscular structures began to show itself. The changes in the size and motor functions of the stomach were progressive to the time of operation, as was the general relaxation in the abdominal walls and ligaments (freely movable right kidney). The secretions up to the time of operation had remained stationary (free hydrochloric acid, 0.1 to 1.1 per 1,000). Notwithstanding the general improvement in the condition of the patient since the operation, we find upon examination one year later that the dilatation still exists and that the subacidity has progressed to a fair state of achylia (free hydrochloric acid, negative; combined hydrochloric acid, 0.1 per 1,000; total acidity, 21–44; albumen digestion, 42 per cent.). The decrease in the secretion of the ferments has apparently not been so rapid.

The motor functions appear to have become normal in all but one case. The same can be said of the size and position of the stomach. In Cases I., III., and IV. the stomach is empty upon lavage within the necessary time limit. In Case I. a small quantity of acid and green fluid was constantly found after all food had passed into the intestine. In Case II. slight atony still remained fourteen months after operation, which incomplete restoration can be traced to improper hygienic surroundings, indiscretions in diet, and the cramped position required by his work, that of tailoring. It is curious that in this case also the size of the stomach should have as materially decreased as in Cases I. and III., in all of which the greater curvature was located at the umbilicus by repeated and various methods of examination. In one case alone (IV.) did the dilatation apparently persist after operation. The greater curvature was still two inches below the umbilicus one year later. Here, however, in marked contrast to Case II., the motility has greatly improved. This improvement, however, is probably more passive than active, and the location of the greater curvature need not necessarily indicate a marked degree of dilatation, as the stomach in this case was more or less vertical from the beginning. The descended and freely movable right kidney still remained as before. In none of these cases is it possible to note the hypermotility claimed by some to exist after operation. The stomachs are empty within the normal prescribed time limit and not before. On the contrary, in Case II., in which the most active and visible peristaltic activity existed before operation, the motility after operation is the most backward in repair.

In order to find the causes which produced this variety of results, it is only necessary to examine closely the conditions existing before operation. We have represented in these cases three distinct types of benign chronic gastric disease. In Cases I. and II.

we have primary pyloric obstruction with secondary hyperacidity and dilatation. In Case III. we have primary functional hyperacidity with secondary pyloric spasm and dilatation. In Case IV. we have primary neurotic atony with secondary subacidity and dilatation. The repeated analyses in Cases I. and II. show the hyperacidity to have been subsequent to and progressive with the obstruction. In Case I., in 1895, a normal acidity existed. The increase in the quantity of free hydrochloric acid could be observed from year to year. In Case III. hyperacidity was constant from April to December, 1899, and previous to that there was a very good history of periodic functional hyperacidity. In the first two cases the hyperacidity was the result of obstruction. In the third case the obstruction was the result of the hyperacidity. In the first two cases we have great dilatation and in the third comparatively slight dilatation.

In Cases I. and II. the hyperacidity has persisted one to two years after operation. In Case I. it has even increased (free hydrochloric acid, 1.5–2 per 1,000). In order to explain these results it will be necessary to refer to the investigations of Boas,[2] Cohnheim,[3] Hayem,[4] Einhorn,[5] and Hemmeter on proliferative changes in the gastric mucous membrane in hyperacidity. Boas speaks of a gastritis proliferus; Hayem of a gastrite parenchymateuse hyperpeptique chloro-organique. From the examinations made by Cohnheim, Einhorn, and Hemmeter of particles of mucous membrane it was found that glandular proliferation existed in from one-half to two-thirds of the cases of hyperacidity. It is immaterial in this connection to know whether this proliferation is in the tubular or the oxyntic cells. Of greater importance, however, as Kovesi[6] properly remarks, would have been the determination of the nature of the hyperacidity—whether primary or secondary.

This explanation of the nature of hyperacidity in a certain class of cases can be applied to our own cases. In Cases I. and II. we have evidence of prolonged irritation of the mucous membrane of the stomach before operation. That this irritation should have led to glandular proliferation is probable, and that the proliferation should persist after operation is natural. Hence we have persistent hyperacidity. We have as facts justifying this assumption not only the progressive increase of the free hydrochloric acid before and its persistency after operation, but also the very stationary and constant quantitative results obtained by analyses during the last examinations made. These results for the total quantity of hydrochloric acid produced were the same for both slight or great stimulation (carbohydrates and proteids). This constancy in production on the part of the gastric mucous membrane is fair evidence of the capabilities of that membrane and also a determining factor in the estimation of its structure.

The causes which led to and produced the results obtained by operation in Cases III. and IV. are of great interest to the internist, for they represent clinical types in which the question of operative interference is largely one of expediency and not of necessity. We have here represented functional disturbances of secretion and motility, which, while not necessarily involving the life of the patient, serve materially to render that life a misery and a burden. It is in these cases that the advice as to operation depends upon severe judgment not only of the actual disease itself, but also of the occupation, social surroundings, and especially the mental tendency of the patient.

In the absence from the records of Cohnheim, Hemmeter, etc., of the actual causes producing the hyperacidity and the history of each case, it will be necessary to accept those cases in which no structural changes were found as purely functional conditions. In Case III. we have such a condition. Here periodic hyperacidity led to chronic hyperacidity, which finally resulted in pyloric spasm and slight dilatation. The discussion of the effect of gastro-enterostomy upon such cases has been elaborate and has involved two questions principally. The one has reference to the seniority of the pyloric spasm or the hyperacidity. The other deals with the effect of operation upon the secretion of the acid itself. Standing for the defence of hyperacidity as a purely functional neurosis we have Bouveret, Fleischer, Schule, Ewald, Riegel, and Pick. On the other side, standing for the spastic theory, are Hayem, Roux, Robin, Doyen, Carle, and Fantino. Midway between these two we have the investigations of Jaworski, Cohnheim, Einhorn, and Hemmeter on the proliferation of the gastric cells. So far as the neurotic and proliferation theories for simple hyperacidity are concerned, it is conceded by gastrologists that both may exist. The discussion has been greatest in regard to the spastic theory, especially in connection with hypersecretion; but as hypersecretion and hyperacidity are allied diseases, the facts deduced will apply to both.

It will be observed that most of the reasoning on behalf of the spastic theory has resulted from observations made at the operating-table. It is not possible, however, to draw absolute conclusions from such observations. That both spasm and hyperacidity should be found at this time is natural; that the spasm should be relieved by an anæsthetic is also natural; but there is no evidence in this that one existed before or produced the other. Cases of simple hyperacidity do not reach the operating-table until sufficient time has usually elapsed for changes to have taken place at the pylorus. On the other hand, many of the observations have been made in cases in which actual tissue change had occurred (I refer to operations for ulcer); and Cohnheim,[7] in a recent article, goes so far as to assert that no dilatation exists without pyloric or duodenal obstruction, however slight this may be.

There can be no doubt about the primary or functional character of the hyperacidity in Case III. This was fully established by long observation before operation. If any doubt still existed as to the nature of this case it has been dispelled by the results obtained from the operation itself. By reported examinations we find that the free hydrochloric acid gradually decreased for six weeks after operation until, on January 31, 1900, it was decidedly subacid. Suddenly, as a result of emotional disturbances, it again becomes markedly hyperacid. This hyperacidity is temporary and slowly disappars as the mental state of the patient becomes calmer. It is hardly possible that a structural change has taken place in the mucous membrane of the stomach with this history. The operation had simply removed one link in the connecting chain of a vicious circle, namely, the possibility of pyloric spasm, and the patient, so far as the gastric secretions are concerned, is placed again in a condition of neurotic and periodic hyperacidity, without pyloric spasm, however. Had the examinations in this case been made for a few weeks after operations only, the result obtained would have been erroneous.

From these frequent examinations and observations the extreme pertinacity of the gastric secretions is demonstrated. This quality is not limited to hyperacidity, as we can see from Case IV. It is generally agreed that subacid conditions remain so after operation. Here, as in hyperchlorhydria, we have primary and secondary subacidities. Primary or neurotic subacidity does not reach the operating-table. Secondary subacidity is the result of the chronic inflammatory conditions involving atrophic changes in the mucous membrane, and these do not come to operation until sufficient structural damage has been done to ex-

clude a possibility of repair. The investigations of Einhorn, Hemmeter, and Martins[1] have demonstrated that partial atrophy of the glandular structure of the mucous membrane exists in from one-half to two-thirds of the cases of achylia gastrica, even in those cases in which no very active dyspeptic symptoms are present.

It was not to be expected, then, that any change for the better would take place in this case. Of interest, however, is the fact that the subacidity existing at the time of operation should have progressed to a condition of anacidity. The operation appears to have had no influence upon the degenerative changes taking place in the gastric mucosa. These structural changes undoubtedly began years before, as the history of the case demonstrates. In 1895 the acidity was normal, even hyperacid at times. This acidity progressively decreased at the same time that loss of tone in the muscular structures and deficiency in peptic power increased up to the time of operation. After operation we have a general improvement in the health of the patient and a considerable gain in weight and no dyspeptic symptoms. Yet in one year we find that the changes in the mucous membrane have advanced so far as to give a fair condition of achylia. It would be impossible to explain this on the basis of continued irritation due to food stasis, for the stomach empties itself within a reasonable time. The simple conclusion to be drawn is that hypertrophic or atrophic changes of long duration may be progressive after operation.

That the continuous hyperacidity and subacidity in these cases should not affect the general health of the patients is not surprising, for in each case the immediate cause of distress has been removed by the operation. It is a matter of common experience to find hyperacidity and subacidity in stomachs which, so far as any subjective symptoms are concerned, are apparently normal. The distress which may be produced by these conditions is purely relative, and both may exist for years without giving rise to any symptoms whatever. In case of hyperacidity it is largely a question of the irritability of the nervous system, both general and local. In cases of subacidity freedom from symptoms depends entirely upon the activity of the muscular structures. On the other hand, it is possible to have pronounced symptoms of hyperacidity in cases in which the gastric analysis reveals normal figures for the secretions. From this it seems almost right to assume, with some of the French authorities, that the normal quantity of acid secreted constitutes hyperacidity in some persons.

The results obtained for the digestion of albumen in these cases, both before and after operation, coincide with those obtained by other recent experimental investigations, and show that the changes which take place in the peptic cells need not be proportional to those found in the acid-secreting cells. In Cases I., II., and III. we have normal results throughout. In Case I. two years after operation the digestion of albumen does not exceed 81 per cent. with a free hydrochloric acidity of 2 per 1,000. The same can be said of Cases II. and III. for both trial breakfast and Riegel meals. In Case IV. we have the same relations. Here the secretion of hydrochloric acid one year after operation is practically *nil*, and yet we find that albumen is digested to the extent of 42 per cent. It would be difficult to state from these figures, however, whether the apparently preserved peptic power is due to a small quantity of pepsin of good quality, or to a large quantity of poor quality. It is impossible to judge the state of the gastric mucous membrane from digestion tests to the same extent as this is done by quantitative acid tests. The action of the acid in the gastric juice is directly proportional to its quantity, whereas the action of the pepsin depends to a considerable extent upon the quality of the ferment. Hence it is that in many instances the results obtained from albumen digestion are not proportional to those found for free hydrochloric acid, and the 42 per cent. obtained for albumen digestion in Case IV. probably means that a certain quantity of pepsinogen of active quality is still being secreted as a result of the general improvement of nutrition after operation.

The same principle may apply to the conversion of the starches. In Cases I., II., and III. we have delayed digestion; in Case IV. there is complete digestion so far as this is possible in the stomach. These cases, then, have followed the general rule in this respect, but here we have extreme conditions of hyperacidity and subacidity. In a good proportion of cases of subacidity it will be found that the conversion of starch does not pass the erythrodextrin stage, whereas, according to rule, it should have been complete. The contradiction can be accounted for only by the inactivity and poor quality of the diastasic ferment secreted with the saliva, especially as in these cases it will usually be found that the peptic power of the gastric juice is reduced and the general nutrition impaired.

The effect of gastro-enterostomy upon the size, position, and motility of the stomach in these cases coincides with the observations made at the surgical clinics. The organ returns to a normal condition of size and motility in those cases in which the enlargement and impaired muscular activity were relative and due to obstruction. These conditions we have in Cases I., II., and III. The reduction of the dilatation was here accomplished by the inherent power of contraction which still existed in the muscular structures of the stomach at the time of operation. Given an opportunity to do so by the removal of the obstruction, they were fully able to redeem the size of the organ. Only in Case II. we find some atony still present at the end of the year. This patient, however, is compelled by his occupation—that of a tailor—to assume a position which is entirely antagonistic to good motor activity of the gastric muscles. This danger existed in Case I. also, but the patient gave up his trade as a cigar-maker, and thus we have a better result. In Case IV. the size of the stomach has not been affected by operation. This was to be expected from the conditions which existed at the time of operation. The enlargement and atony were positive and part of a constitutional condition which had existed for years. There was no power left in the muscular coats to contract; hence the repair is slow in this case. The stomach, however, even in this case empties itself fairly well. This improvement in motility is probably more apparent than real, and due to a large extent to gravity. An examination of the muscular activity of the stomach before and after operation by the introduction of a Hemmeter intragastric bag would be of interest.

The more or less constant presence of bile in the gastric contents after operation has been noticed by most observers. It is generally acknowledged that it causes no disturbance. It has not in these cases. According to Boas, the objectionable feature connected with the presence of bile in the stomach lies in its alkaline reaction and in the danger of precipitation of the pepsin. In cases of hyperacidity after operation the first property need hardly be feared. In cases of subacidity the conditions are somewhat different. Here the neutralizing effect of the bile might be offensive, but is counteracted in part by the inhibitory action upon the fermentation to which these cases are prone, especially if the atony is persistent.

The regulation of the action of the intestines is one of the best results obtained by gastro-enterostomy. This effect is generally reported in all the statistics. It was very marked in our own cases. The reasons for this relief from pre-existing constipation vary ac-

cording to the conditions at the time of operation. The constipation of the first three cases of pyloric obstruction was spastic in its nature. It was due not so much to the obstruction in the passage of food through the pylorus as to a condition of tonic spasm induced all along the intestinal tract by the spasm at the pylorus and the fixation of the abdominal muscles as the result of pain. We have evidence of this in the small lumpy or lead-pencil character of the stools in the first three cases. It was a condition of secondary enterospasm, so to speak. This tonic condition was removed by the elimination of the pylorus by operation, and in a short time the stools not only became regular but normal in size and consistency.

In Case IV. the constipation was atonic. It was part of a general muscular relaxation. Here the stools were large in calibre and occasionally fermentative diarrhœas would supervene. After operation we find normal and regular stools, due to the general improvement of muscular activity, both voluntary and involuntary, the result of the improved nutrition. This regulation of the action of the bowels is one of the most salutary effects of the operation of gastro-enterostomy, and to it in many cases can most of the benefits of operation be ascribed.

The most complete reports and statistics of the operation of gastro-enterostomy have come from the clinics of Czerny,[9] Mikulicz,[10] Hartmann and Soupault,[11] Carl and Fantino,[12] Doyen,[13] Tricoms,[14] and others. Practically their cases may be divided into three classes: 1st, operations of necessity; 2d, operations of emergency; 3d, operations of expediency. By far the great majority of the cases reported has belonged to the first two classes. The effect of operation upon the subsequent secretory functions of the stomach in these cases, however, is a matter of secondary importance. The life of the patient is involved, and, whatever may be the ultimate result, the pyloric obstruction or gastric perforation or hemorrhage must receive immediate attention.

It is in the third class of cases, as represented in Cases III. and IV. of this paper, that very definite rules for operating are desirable. The results desired in these cases are remote, not immediate. As these results, as we have seen in some cases, depend upon the actual condition of the mucous membrane at the time of operation, and also the course of the disease for a long time before operation, it now appears desirable to eliminate from the statistics all those cases in which it has not been possible to ascertain the actual structural condition of the mucous membrane of the stomach by repeated analyses for months prior to operation. It is unfortunate, therefore, that we should miss from many of the reports the detailed and serial analyses and observations of the internist before operation, for it is only in this way that a definite knowledge of the actual condition of the mucous membrane can be obtained. A few gastric analyses made immediately before operation are of small value in this respect, especially in neurotic cases. The stomach reacts to the emotions somewhat like a lacrymal gland. It either secretes profusely or very little. It is for this reason that I have come to discard the results obtained by a first analysis of the gastric contents. They are generally erroneous. In most cases repeated analyses at stated intervals and after various meals are necessary to secure sufficiently accurate figures which may be used in diagnosis and prognosis. Especially is this the case as most of us have not the time to look for or the courage to scrape off particles of mucous membrane for microscopical examination.

That the results to be obtained by gastro-enterostomy and the prognosis to be given depend upon this knowledge has been sufficiently demonstrated. Whether or not a hyperchlorhydria is to recede after operation depends in a certain proportion of cases upon the structural changes which have taken place in the mucous membrane. It has even been shown that it may increase, and this brings us to the absolutely independent character of the gastric secretions, and the progressive nature of structural changes once begun, even though the cause for the beginning of these changes has been removed by operation. In Cases I. and IV. we have diametrically opposed conditions. In one we have hyperacidity due to cell proliferation, and in the other progressive subacidity due to cell atrophy, and in both the most marked improvement in the general nutrition and local distress; yet in both, one and two years after operation, we find that the abnormal conditions of secretion have progressed in their respective directions. This obstinacy on the part of the secreting cells of the gastric mucous membrane is a matter of common observation in the treatment of a considerable proportion of chronic gastric affections, and continues after the active dyspeptic symptoms have disappeared.

It would be impossible to draw general conclusions from the observation of this limited number of cases. It can only be said that they have been closely followed, and, as representative of certain well-known types of chronic gastric diseases to which gastro-enterostomy is applied, may be of some service in the formation of rules for prognosis and advice.

A NEW PHYSICAL SIGN IN DISLOCATION OF THE HEART; GASTRECTATIC DYSPNŒA AND PSEUDO-ANGINA.

By ALBERT ABRAMS, A.M., M.D.,
SAN FRANCISCO, CAL.

Acute or chronic dilatation of the stomach is a frequent cause of dyspnœa and even asthma. An asthma of gastric origin is the asthma dyspepticum of some writers. Asthma of gastric genesis is, however, caused less often by gastrectasis than by the absorption and irritation of products the result of gastric indigestion. The latter observation is based only on my individual experience. In my case-book, I have records of a number of patients, especially children, with asthmatic symptoms in whom gastrectasis did not exist, and who were cured by treatment directed solely to the stomach —systematic lavage and a suitable dietary. I have called difficult breathing sequential to gastric dilatation, gastrectatic dyspnœa. Many sufferers from this form of dyspnœa make no mention of dyspeptic symptoms, the latter being masked by pressure signs. Such individuals are usually recruited from the ubiquitous neurasthenics. Their pneumatosis is sudden in origin and attended by a feeling of weight or pressure in the precordia or sternal region. Eructations of gas mark the relief of the paroxysm. In some instances the symptoms are protracted, the patient being unable to get rid of the gases owing to spasm of the sphincters

of the stomach. Gastrectatic dyspnœa is caused, as I have assured myself after examination of a number of patients, by dislocation of the heart upward by a dilated stomach. Some years ago, I reported a case[1] of gastroptosis and mercycismus with voluntary dislocation of the stomach and kidney. This phenomenal case taught me one fact in particular, viz., the ease with which dislocation of the heart could be induced by a dilated stomach. The individual in question could, by buccal insufflation of the stomach, cause his heart to disappear behind the lungs, so that precordial percussion yielded absolutely no dulness. This case

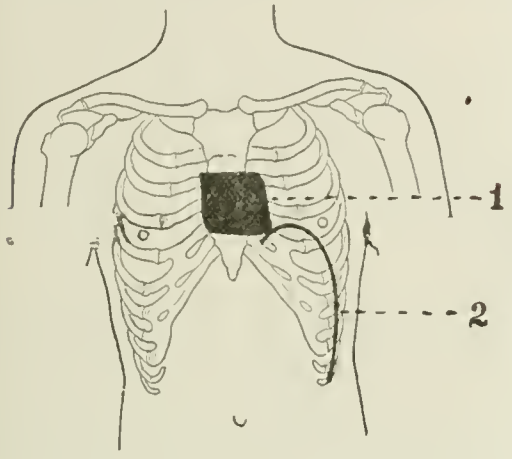

Fig. 1.—Effect of Stomach Insufflation on the Heart; 1, Radioscopic appearance of the heart; 2, Outline of the fundus of the stomach.

directed my attention to a correct investigation of all individuals presenting themselves for the treatment of slight dyspeptic symptoms in whom sternal pressure and dyspnœa, especially in walking, were the chief subjective symptoms. In nearly all such individuals, the diminished area of cardiac dulness with its congeneric sign, viz., enfeebled heart tones, bore a distinct relation to the severity of the pressure symptoms. The removal of the ingesta and gases from the stomach usually restored the heart to its normal position and the feeble heart tones became strong. To detect quickly a dilated stomach encroaching on the thoracic viscera, the percussion method of Ferber[2] is highly recommended, although my experience with this procedure has often been negative. Ferber found that the circular tympanitic stomach-lung region formed

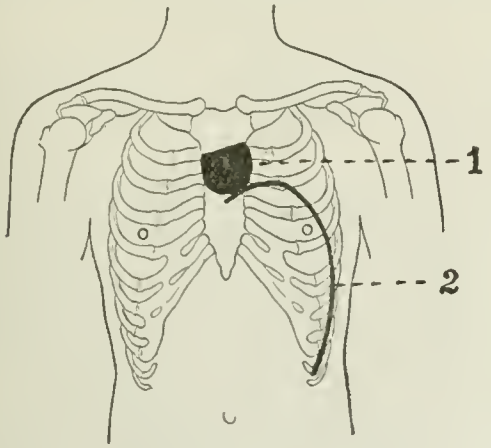

Fig. 2.—1, Radioscopic appearance of the heart after administration of a Seidlitz powder; 2, outline of the fundus of the stomach.

by the stomach beneath the lower lobe of the left lung gradually disappears behind the axillary line if the stomach is normal, but if the latter is dilated it may be traced to the vertebral column. The following illustrations describe more fully than words the influence of a dilated stomach on the position of the heart. They are through reproductions from the fluoroscopic picture. In the average examination of the chest by means of the Roentgen rays, that portion of

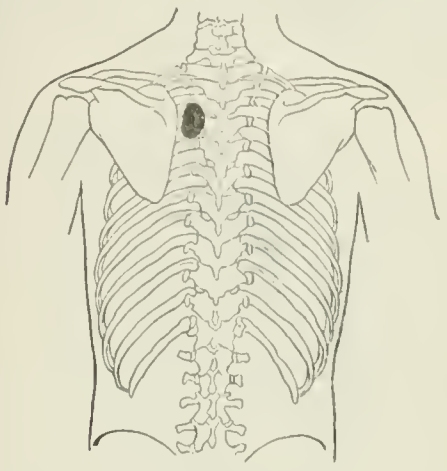

Fig. 3.—Patch of Dulness in Dislocation of the Heart Upward. Patient in the erect position.

the stomach which is in direct contact with the chest wall, occcupying the space of Traube, is obscured by the shadow cast by the spleen. There is a small proportion of cases in which a considerable area of stomach-illumination is shown by skiascopy. This condition is engendered by the favorable position of the spleen, which does not lie sideward and upward from the stomach but downward and outward from the latter viscus. It has been my good fortune to have met with, in my skiascopic examinations, two persons in whom the illuminated stomach area in Traube's space corresponded with the normal dimensions of the stomach in that region, a condition which I attributed to one of four things, viz., favorable location of the spleen, absence or atrophy of the spleen, and the presence of rudimentary splenules. In the examination of one of the individuals, the unusual phenomenon was utilized in studying a case of nervous eructation.[1] In the other patient,

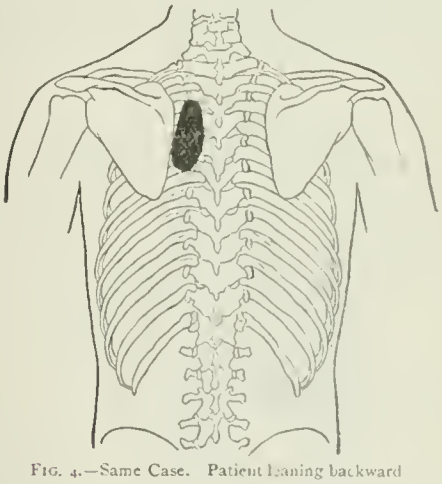

Fig. 4.—Same Case. Patient leaning backward

artificial distention of the stomach was produced by means of a Seidlitz powder. The illustrations (Figs. 1 and 2) demonstrate most forcibly how sudden death may occur after a heavy meal if the individual is a sufferer from indigestion with a weak heart. Little or no detailed reference is made to gastrectasis in the literature as an etiological factor in pseudo-angina pectoris, although in my own experience I have frequently encountered cases of pseudo-angina which were cured by treatment directed solely to the stomach

or to a neurasthenic condition which was primarily a factor in the distention of the stomach by gases. The sign of Ferber has been most unsatisfactory to me in detecting a dilated stomach fundus. Repeated examinations of the thorax after artificial distention of the stomach with air failed in a number of instances to confirm the constancy of this sign. Diminished area of cardiac dulness and enfeebled heart tones which

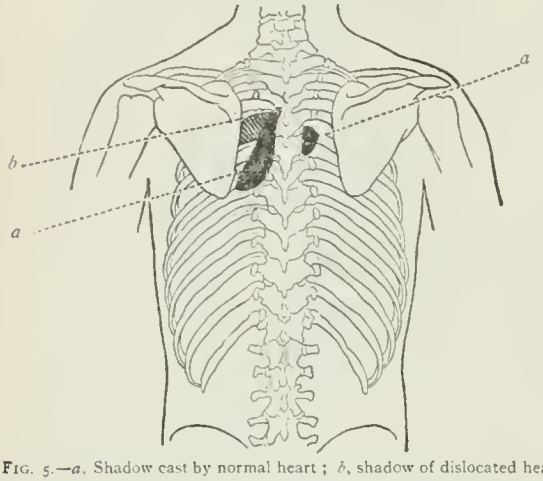

FIG. 5.—*a*, Shadow cast by normal heart; *b*, shadow of dislocated heart.

assume an embryocardial character are more trustworthy objective symptoms.

There is a new sign to which I wish to direct attention. When the heart is dislocated upward by a dilated stomach, a patch of dulness and even flatness may be detected in the interscapular region on the left side, about midway between the vertebral column and the internal border of the scapula. This is the usual site, although the patch of dulness may reach a point on a level with the spine of the scapula. The dull area may vary in size from that of a silver dollar to the entire space between the scapula and spine. It always disappears to be replaced by the normal lung resonance when the patient leans forward, reappears when the erect posture is again attained, and the area of dulness is greatly increased by directing the patient to bend backward. Over the area of dulness, bronchial respiration is heard, but this likewise disappears when the patient

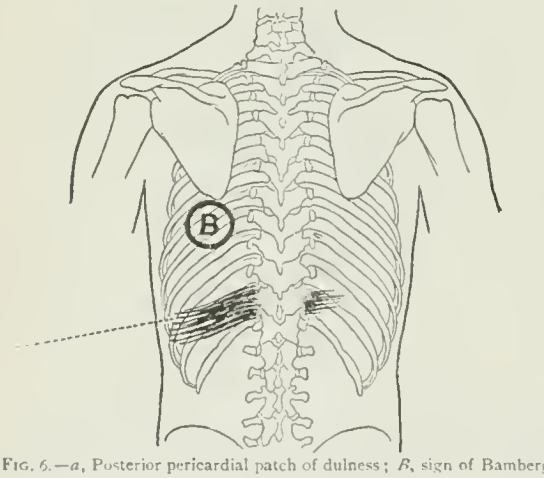

FIG. 6.—*a*, Posterior pericardial patch of dulness; *B*, sign of Bamberger.

bends forward or becomes increased in intensity when the patient leans backward. The accompanying illustrations (Figs. 3 and 4) serve to exemplify the subject-matter. The cause of the dulness is compression of the lung by a dislocation of the heart upward. This sign is constantly present. That the patch of dulness is actually caused by lung compression from a dislocated heart, I have assured myself synthetically by introduction of the stomach tube into the stomach and distending the latter viscus by air, by which means I could invariably reproduce the clinical phenomena, viz., dulness in the left interscapular region disappearing when the patient leaned forward, increasing area of dulness when the patient leaned backward. Corresponding to the percussional sign, bronchial respiration is heard with resumption of vesicular breathing when the forward attitude is assumed. Withdrawal of air from the stomach is attended by a disappearance of the phenomena. One may follow the foregoing procedure by aid of the Roentgen rays, and note the upward dislocation of the heart by the distended stomach. The degree of heart dislocation viewed from the back is surprisingly slight, and it would appear theoretically to be unable to account for the lung compression. If the dislocation is protracted, it will be found difficult to differentiate the shadow cast by the heart and the compressed lung. Fig. 5 represents the shadow cast by the normal heart on the posterior surface of the thorax. The shaded area is the dislocated heart after artificial distention of the stomach.

The patch of dulness caused by upward dislocation of the heart may be confounded with atelectatic zones which are frequently present in this region. I have referred elsewhere to these zones.[1] The zones of atelectasis, however, disappear after repeated forced voluntary inspirations, or by means of what I have called the lung reflex,[2] and are in no wise influenced by the position of the patient. The only two physical phenomena in any way associated with my sign are the posterior pericardial patch of dulness and the sign of Bamberger, signs which arise in pericarditis with effusion and are caused by the exudate compressing the lung. In pericardial effusion the sign of Bamberger is important. When the patient is in the erect posture, an area of dulness about the size of a silver dollar can be outlined at the angle of the scapula, over which increased fremitus and bronchial breathing may be elicited. If the patient bends forward, the signs disappear, to reappear when he sits upright.

TWO CASES OF INTESTINAL OBSTRUCTION FOLLOWING VAGINAL HYSTERECTOMY, AND ONE AFTER PELVIC ABSCESS, WITH A SECONDARY OPERATION IN EACH CASE.[3]

BY A. GOLDSPOHN, M.D.,

CHICAGO,

PROFESSOR OF GYNÆCOLOGY, CHICAGO POST-GRADUATE MEDICAL SCHOOL; SENIOR GYNÆCOLOGIST TO THE GERMAN HOSPITAL, AND ATTENDING GYNÆCOLOGIST TO THE POST-GRADUATE AND THE CHARITY HOSPITALS OF CHICAGO.

A VERY good and recent French thesis upon postoperative intestinal obstruction, by M. le Dr. E. Lenclos,[4] enumerates cases of ileus as follows: 57 after ovariotomy; 16 after salpingectomy; 8 after abdominal ablation of uterine fibroids; 6 after abdominal hysterectomy; 7 after radical cure of hernia; 4 cases after cœliotomy for strangulated hernia; 3 after operations for appendicitis; 1 each after hysteropexy, Cæsarean section, and transperitoneal nephrectomy; and 37 cases of ileus after vaginal hysterectomy. Of the last-named number evidently the largest proportion of cases have occurred in the French-speaking countries or after French technique of vaginal hysterectomy.

[4] Gazette hebdomadaire de médecine et de chirurgie, 1900, t. 47, pp. 37–44.

But the following isolated and interesting cases, among others, in the literature of this subject, in which a secondary operation for relief of the obstruction was performed, are certainly also included in that collection: L. Landau[1] reported a case in 1888 done with clamp forceps, and the associated intraperitoneal gauze drain. It was progressing normally. The forceps were removed after one and two days. The patient got up on the fourth day and walked about for a drink. Soon after symptoms of ileus and peritonitis followed, and progressed. On the seventh day a loop of ileum was found adherent in the funnel of the wound, and was liberated by abdominal section. But the patient died next day.

P. Reichel[2] records three cases of ileus after vaginal hysterectomy, occurring in 1887 and 1888, in Olshausen's clinic. No clamps were used in these cases, but the peritoneal cavity was left open and drained by gauze. In two of these a secondary cœliotomy was done, but the first patient died on the table on the seventh day, and the second one died twenty hours after the operation on the eighth day. Neither of them had passed gas or fæces, aside from the contents of the colon, since the first operation. No rhythmical colic pains were mentioned, nor was there any pyrexia or marked tenderness of the distended abdomen. The first had a rapid pulse from the beginning, and both were nauseated or vomited early.

In 1887 A. P. Dudley[3] (New York) did a vaginal hysterectomy for carcinoma. Hæmostasis was secured by ligatures, and an intraperitoneal gauze drain was inserted. Six months later, while exerting herself, the patient felt something give way in her pelvis, and thereafter suffered from intestinal obstruction of variable degrees for four months, until a fecal fistula into the vagina developed spontaneously. This was successfully cured, one year after the vaginal hysterectomy, by abdominal section and resection of the injured small intestine, performed by a California surgeon.

In 1889 H. C. Coe[4] performed vaginal hysterectomy for an adherent cancerous uterus associated with a small ovarian cyst. Hæmostasis was secured by four pairs of forceps, left in for forty hours, and an intraperitoneal and vaginal gauze drain was placed. The patient took fluids by mouth from the beginning, and was in good condition until the fourth day, when distention and rise of temperature occurred. These became less the next day after cathartics and enemata, but returned more severely, together with an accelerated pulse, on the sixth day, when the abdomen was opened and a portion of the ileum found adherent to the right edge of the wound and severely kinked. There was no extensive peritonitis. The intestine was liberated, the abdomen irrigated, gauze drainage renewed into the vagina, and the abdomen closed. The patient died next morning from shock.

In 1896 John A. Prince[5] (Springfield, Ill.) did vaginal hysterectomy for chronic ovarian and tubal disease. Hæmostasis was secured by forceps, removed on the second day. The patient passed gas freely from the first day, and had two good bowel movements on the fourth day. But tympanites developed on the eighth and complete obstruction on the ninth day. On the tenth day the doctor passed his hand (in narcosis) up the vagina, and the fingers into the pelvis, breaking up the adhesions, which appeared to be composed entirely of omentum. He came upon a collapsed portion of small intestine, and made a lateral anastomosis between this and an adjacent distended portion of small intestine by means of a Murphy button within the vagina. Natural evacuations followed, but a free fecal fistula supervened. However, a spontaneous recovery resulted finally.

In a somewhat hasty review of the literature of the past twelve years, I have found only this one case (of Dr. Prince), in which a secondary operation was performed for ileus successfully within ten days after vaginal hysterectomy, and not merely for this condition as a later sequel of that operation. To this case I can add another successful one by abdominal section, and also two unsuccessful ones.

Case I.—Mrs. F. S——, aged thirty-four years, multipara; total vaginal hysterectomy for chronic metritis (fibrosis uteri); pyosalpinx of one side, and cystic ovary of the other side. The uterus was high up, anteverted, and the broad ligaments were difficult of access. Therefore a broad-ligament forceps was left on the upper portion of the broad ligament of one side, but in its base and in the entire opposite side preventive or antecedent[1] hæmostasis was secured by ligatures, with difficulty. The patient bore the operation well, and continued to be in a satisfactory condition for two days, except that the much-desired passages of gas failed to come after the usually very effective enemata that were begun after twenty-four hours, and repeated at intervals of four to six hours. The forceps was removed after forty-eight hours, and about ten small, hourly doses of calomel and soda were next given, followed by several doses of magnesium sulphate. These things started the vomiting, but did not secure the needed evacuations nor reduce the rising tympanites. There were no decided tenderness of the distended abdomen at this time (third and fourth days after operation), and no colicky pains, but much discomfort from the distention. The temperature during the first two days did not rise over 101° F., and the pulse ranged from 90 to 110. After the first nausea from the anæsthetic passed off, there was no vomiting, and liquid food was taken satisfactorily up to fifty-six hours after the operation, when the vomiting began and continued, with growing tenderness of the tympanitic abdomen, with some rise of temperature and a greater acceleration of pulse. A high and somewhat forcibly retained half-gallon enema of water, with essence of peppermint, afforded no real improvement. Hot fomentations and turpentine stupes gave only slight and temporary relief, and did not improve the general condition, which was rapidly growing worse, with the signs of peritonitis supervening upon those of ileus. Therefore I opened the abdomen eighty-four hours after operation. The small intestine was severely distended and intensely injected, with loss of lustre, and some threads of fibrin upon the loops nearest the pelvis. There was a small amount of fluid exudate. A loop was adherent in the bottom of the cul-de-sac, where it appeared to have been compressed by the gauze drain, but it was not completely occluded and was easily raised. Through drainage from the abdominal incision into the vagina was introduced. The patient was now severely shocked, but hypodermics of strychnine and camphorated oil, given alternately and liberally, afforded temporary improvement. But no satisfactory evacuations from the bowels were obtained, notwithstanding numerous colonic flushings. The signs of general peritonitis grew continually, and terminated in death about thirty-six hours after the ventral section.

Case II.—Mrs. P. P. C——, aged forty-three years. The patient was fairly nourished and vigorous, but had some albumin in the urine, and had had a rise of temperature recently from the intrauterine septic

[1] Antecedent as distinguished from consequentive hæmostasis, as is the case in the technique of Doyen, in which the uterus is drawn down into the vulva and is "pedicled" upon the broad ligaments before the latter are clamped or tied off.

condition. On January 25, 1900, a large metritic and severely adherent uterus, containing a necrotic and suppurating submucous fibroid, the size of a large hen's egg, was removed by the vagina, together with the very adherent and degenerated adnexæ and an ovarian cyst of the left side. (The patient had had repeated attacks of pelvic peritonitis previously.) The uterine arteries were secured by two ligatures on each side, and the upper portion of each broad ligament and the ligamentum infundibulo-pelvicum beyond the tube and ovary of each side were secured by a curved broad-ligament forceps. A small forceps was also allowed to remain upon a branch of the right uterine artery, that was not caught in the ligatures. These forceps were removed after forty-eight hours. The raw wound surface in the pelvis was very large, and the opening in the vaginal vault was carefully sponged out, while the patient's body was placed in a moderate Trendelenburg position to cause the small intestines and omentum to recede, and not to become entangled with the sponges and the subsequent gauze packing or drain which was introduced before the patient was returned to the horizontal position, thus giving the least possible chance for the intestine or omentum to become mingled with it. The general condition of this patient was absolutely perfect for eight days. Very satisfactory passages of gas and stool came after enemata after twenty-four hours, and on every day after that until the end of the eighth day. Up to that time her pulse ranged between 75 and 90, and the temperature between 98.6° and 99.8° F., reaching 100° F. only once in the first forty-eight hours, with a pulse of 100. The excretion of urine was ample. After the immediate effects of the narcosis, there was no vomiting, and the amount of nourishment taken and relished was very satisfactory. But with the ninth day some distention and rhythmic colicky pains and some tenderness of the lower abdomen and nausea and vomiting began, with a rise of pulse to 100, and temperature to 100.8° F. As a saline, a laxative, vigorous high enemata, and turpentine stupes secured only a temporary improvement, and no gas had been passed for thirty-six hours, while the abdominal distention, colicky pains, and vomiting were becoming worse, I fortunately decided to wait no longer, and performed ventral cœliotomy on the tenth day, although the pulse at the time was only 100 and the temperature 100.8° F. per rectum. More than a pint of free fluid peritoneal exudate at once escaped from the incision. All the small intestines that came into view were intensely injected, and the peritoneal lustre was absent over extensive areas of their red surfaces, which bore strands of fibrin, chiefly along the lines of junction of two opposed surfaces. Two loops of ileum, with a mass of omentum, were adherent to the posterior edge of the vaginal wound, and were severely kinked and drawn upon. Detachment wounded their serous and muscular coats. When these surfaces were repaired by superficial stitches of fine silk, and when the peritoneal exudate had been sponged out and the most suspicious parts had been treated with peroxide of hydrogen, the gauze drain into the vagina was renewed, and three gauze drains from different points in the abdomen, so placed as also to cover the sutured areas, were guided out of the abdominal wound, which was closed only about one-half. The patient bore the operation very well, with camphor and strychnine hypodermically. Satisfactory evacuations came in six hours afterward. The pulse, at first not at all accelerated, rose to its maximum of 115 in eight hours, when the temperature was 99.8° F. A slight rise of temperature with a pulse near 100 continued for about five days. A large amount of fluid was discharged by the vaginal and the abdominal gauze drains. The abdominal wound was closed completely under anæsthesia, about twelve days after it had been made, but the gauze drain beneath the bladder into the vagina remained a few days longer. The patient left the hospital and the city thirty-two days after the first operation, with all wounds closed, and in the best of spirits.

Case III.—Mrs. A. J. S——, aged twenty-seven years, IIpara, with one induced abortion at three months, six months ago. Before that she had been generally healthy, and without hereditary taint. The patient submitted to instrumental interference on the part of a notorious midwife, for supposed pregnancy, soon after one cessation of menses. This was followed by a continuous and profuse bleeding for three weeks, with constant pain; and after fever, vomiting, and persistent constipation had supervened. Dr. H. S. Barnard, succeeding a former attendant, recognized a large pelvic abscess and transferred the patient to the Post-Graduate Hospital. On March 9th I made a two-and-a-half-inch transverse incision in the posterior vaginal vault, back of the uterus, with a Paquelin cautery, opened into the large multilocular abscess with my fingers, broke down some septa, and evacuated at least a gallon of pus. The abscess cavity and the vagina were then packed with sterilized iodoform gauze, which was renewed in the vagina every second day, and was all removed after a week, when a double soft-rubber drainage tube was introduced into the abscess cavity, extending within the vagina almost to the vulva, so that an irrigator tube could be inserted into one of its terminal openings, and the cavity irrigated daily. Sixteen days after operation, when her general condition had become quite normal, although still quite feeble, a difficulty arose with the bowel evacuations. Calomel and salines were followed by nausea and vomiting, and the high enemata were often mostly retained, or came away in a drizzling manner, which, together with the contour of the abdomen, suggested a filled colon and an obstruction at the sigmoid flexure. This I thought to be the trouble and to be caused by some involvement of the sigmoid in the retracting abscess walls. This view of the disorder, and the fact that a high rectal tube could, sometimes at least, be run up into or through the sigmoid, as shown by digital exploration in the vagina and the cul-de-sac, induced me to delay interference for about sixty hours after fæces were first vomited. The pulse during this time ranged from 104 to 130, and the temperature from 98.4° to 101° F. On March 29th (twentieth day) I made an incision suitable for left inguinal colostomy, and at once came upon a greatly distended and inflamed small intestine, which led down to an acutely flexed portion whose serous coat was pulled out in form of a band, that was attached to something in the abscess wall below. The obstruction was almost complete; but when the band was severed the collapsed and strictured portion of small bowel could be again distended by compression of the dilated gut; and stitches to repair the wound in the serous and muscular coats were all that were needed. But the sutured part, as well as all the rest of the intestine that came within the wound, was clearly involved in marked peritonitis. As there was no liquid exudate, I placed no drain, but closed the wound entirely. The patient rallied from the severe shock, and satisfactory bowel evacuations came spontaneously after five hours. Nevertheless, coolness of skin and extremities, with a very rapid pulse and other evidence of severe infection and general peritonitis, soon followed, and continued until death—seventy-two hours after the ventral section. Autopsy by Professor Zeit, pathologist of the Post-Graduate Medical School, twenty-four hours after death, showed no free gas in the abdominal cavity. The small intestines were greatly distended and involved in general peritonitis,

being coated with purulent fibrinous exudate. There was no apparent leakage of the ileum at the point of suturing, which looked greenish-black, and was surrounded with a purulent necrotic area. After the intestines were taken out and detached from their mesentery, a perforation, the size of a small coffee-bean, was found six and a half feet from the stomach end. The left side of the pelvis contained a large abscess cavity, with some greenish-yellowish pus that had an ammoniacal odor. In the walls of this cavity the small intestine and also the vermiform appendix were extensively engaged. Professor Zeit says the operation was not successful, because it was done too late, *i.e.*, upon structures already infected.

Observations.—1. According to the showing of Lenclos, ileus is more frequent after vaginal hysterectomy than after other abdominal sections. This is as we could expect, chiefly in all cases in which the abdominal or pelvic cavity is not closed; for in these cases two or three of the chief causes of peritoneal adhesions are quite generally present, *i.e.*, (*a*) raw surfaces, (*b*) infection, and (*c*) a foreign body (the drain).

2. Inasmuch as we know that the physiological economy of the abdomen demands that the different portions of the small intestines shall be free to migrate from place to place, as is painfully illustrated by my third case, therefore any opening of the abdominal or pelvic peritoneal cavity is deplorable, that engages any portion of the small intestine to assist in closing the opening or wound. This is regularly the case in vaginal hysterectomy, as ordinarily performed, and as is necessarily done in all cases of this operation in which there are extensive abraded surfaces, or in which septic features are present in the case. But in all other cases of this operation, when no intraperitoneal drain is needed, it is a just requirement that the peritoneal cavity be sealed by a closure of the wound in the peritoneum by coaptation of its edges; and that the use of hæmostatic forceps or clamps, as far as it interferes with such closing of the peritoneum, should be avoided as far as possible. I do not, from my experience, find it necessary or desirable to close the opening in the vaginal vault, but prefer to let this and the broad ligament wound drain into the vagina.

3. The secondary operation for the relief of post-operative ileus, to be successful, must be performed early, before the mechanical obstruction has caused infection and paralysis of the bowel (peritonitis).

4. When this difficulty arises early—within three to four days after an abdominal or pelvic operation, *i.e.*, the time in which post-operative peritonitis can also be expected—it will often be difficult to exclude the latter, which also causes similar symptoms.

5. The symptoms and signs which speak mostly for ileus are: Abdominal distention without marked tenderness to touch on gentle pressure; the presence of rhythmical colicky pains; a slow pulse that is not wiry; fecal vomiting; vermicular motion of the small intestine, seen or felt through the abdominal wall; increased proportion of indican in the urine.

Incipient Insanity.—T. Outterson Wood describes the disorder characterized by a feeling of unhappiness, a dampening of buoyancy of spirits and healthy, hopeful looking forward, with a loss of power in fighting against the weight of despondency. The expression of the patient's face is that of unhappiness and uncertainty, and the attitude of the body is that of listlessness and want of energy, showing a flaccid condition which distinguishes it from the well-known condition of flexion so typical of the pronounced melancholic. Another striking difference between this state of depression and melancholia proper is that in melancholia there is a characteristic tendency to tears. The danger is in the recurrence and persistence of attacks of depression until they gradually drift into the depths of melancholia. Drugs are useless. The general health should be improved and a healthy action of the various excretions encouraged, with change of scene, change of daily routine and work, open-air living, exercise, and cheerful surroundings.—*Treatment*, July, 1900.

A New Method of Treatment of Initial Syphiloma.—Leone Levi claims that his method is new, the means used for its application not being new, however. He cauterizes the syphiloma, preferably by means of the galvano-cautery. Certain practitioners in the past cauterized a syphiloma perhaps once; the author does it, if necessary, a thousand times, until the treatment determines an intense local inflammation of the tissues. This makes of the syphilide a mere local infection, preventing constitutional infection with all its consequences. He describes his method in detail, and claims absolutely successful results in thirty-two cases.—*La Riforma Medica*, July 19, 1900.

Concomitant Measles, Chickenpox, and Smallpox.—Otto Lerch relates a case which, so far as his search goes, shows no parallel in literature. A twelve-year-old boy, after fever, chill, etc., showed a crop of vesicles; five days later, after headache, nausea, and vomiting, the temperature rose from normal to 104° F., and signs of measles appeared. In another instance there was coexistence of measles and varioloid, and in one family the writer observed cases of measles, smallpox, and chickenpox, and he believes they may all coexist in one individual.—*New Orleans Medical and Surgical Journal*, August, 1900.

Pseudo-Membranous Bronchitis.—A case of this unusual affection is reported by Joncheray, whose patient was a man aged fifty-seven years. The author says that it is necessary to distinguish between the acute and chronic forms of the disease. The membranes may suggest diphtheria, and we must examine for the Loeffler bacillus, look after the lymph nodes, and if necessary make use of serum treatment to clear up the diagnosis. Another form is that due to the aspergillus fumigatus, but examination will reveal the parasite, and it can be cultivated outside the body. When no membranes have appeared, it is necessary to differentiate from foreign bodies, ingestion of caustic liquids, cicatricial contraction, tumors, glottic spasm, and rarely tracheal ozæna.—*Revue Hebdomadaire de Laryngologie*, July 28, 1900.

Typhoid Mastitis.—Luigi Fornaca reports a case in a woman aged forty years. On the twenty-ninth day of the disease, the patient being convalescent, pains appeared in the right breast and soon became extreme, and on the following day the breast was greatly swollen. An exploratory puncture five days later showed the tissues to be hard and resistant; three drops of a sero-purulent fluid were obtained, and cultivated in ordinary broth. The left breast became involved sixteen days after the right, and both tumors became indolent, although remaining enlarged and hardened. The fluid cultivated on bouillon showed a micro-organism which in appearance, reactions to stains, and action upon guinea-pigs in every way resembled Eberth's bacillus.—*La Riforma Medica*, July 27, 1900.

Trinitrin in Melancholia.—Guiseppe Paoli has found this drug to be of great service in the type of melancholy characterized by attacks of "anxiousness," the agony of mind being largely due to vasomotor disturbances. To patients who are periodically subject to grave exacerbations of their condition, whose pe-

ripheral blood-vessels are evidently in a spastic state, which becomes much aggravated during the attack, he gives treatment the object of which is to prevent the attacks and to overcome the permanent constriction of the vessels. With this object in view, he puts them on a milk diet, and prescribes two spoonfuls a day of the following potion: "One-per-cent. alcoholic solution of trinitrin, gtt. 30; water, 300 gm." This is given for the first ten days of each month, a mild iodine treatment being given the other twenty days: "Iodide of sodium, 10 gm.: water, 300 gm.; 2 spoonfuls a day." Meanwhile glycero-phosphates with arseniate of strychnine are given hypodermically to counteract the action of the treatment on the blood corpuscles. The cardiac and renal functions are closely watched during the treatment.—*La Riforma Medica*, July 28 and 30, 1900.

A Disease Resembling Acute Leukæmia.—Stephen reports the case of a middle-aged woman who died after a short illness with every evidence of great prostration, but no focalizing symptoms or physical signs. The microscopic examination of the blood revealed a diminution of the red cells and an increase of the leucocytes; the small lymphocytes being scanty, but the eosinophiles present in abnormally large numbers. The main feature of interest, however, lay in the fact that though many of the red cells contained what were undoubtedly nuclei, others exhibited what the author believes to be amœboid parasites. These were also to be found in some numbers lying free between the cells, and Stephen considers himself justified in regarding them as the cause of the disease, to which he applies the name of proteosomiosis.—*Wiener klinische Rundschau*, July 22, 1900.

Subacute Tuberculosis of the Pharynx in Childhood.—Carlo Comba reports three cases of this affection, which is rare in childhood, only fourteen cases being found in medical literature. In these three cases the process was secondary to tuberculosis of the air passages and the digestive tract. The subjective symptoms are sharp pains in the affected region, which are increased during deglutition, so that swallowing is sometimes absolutely impossible. Should the soft palate be involved, it becomes paralyzed. An examination of the pharynx in the early stages will show grayish-yellow nodules, composed of soft tissue which easily bleeds. At a later stage these ulcerate and leave cavities with irregular margins, containing a detritus of caseous substance and muco-pus. The surrounding mucosa is swollen and red. The cervical glands become swollen and sometimes suppurate. The diagnosis is not difficult, especially when there are marked symptoms of tuberculosis in other organs, and will be materially assisted by bacteriology.—*Lo Sperimentale*, vol. liv., No. 3, 1900.

The Hygiene of Obesity.—K. von Noorden divides the treatment of those suffering from obesity into three headings. First and perhaps most important in preventing and removing abnormal deposits of fat is the matter of exercise, but this requires careful regulation and adjustment according to each individual's needs and capabilities. The best and also the most universally applicable form of exercise for this class of patients is pedestrianism, and especially hill-climbing. It is easy to determine the length of walk to be taken, the character of the ground to be covered, and the length of time consumed; to avoid overtaxing the heart, thorough ventilation of the chest by deep and regular respiration must be insisted on. The second element in the treatment involves the care of the skin. Fat persons are especially liable to some forms of skin diseases, notably seborrhœic and intertriginous eczema. In the treatment and prophylaxis of these scrupulous cleanliness and hydrotherapy are of the greatest value. Regular baths, frictions, and cold douches are useful for the hyperidrosis commonly observed; if these are insufficient, Turkish baths, small doses of atropine, and restriction of the fluids imbibed are indicated. The third therapeutic factor to be considered embraces the question of diet. In addition to a careful selection of the articles of food allowed, it is of greatest service to make each meal very small in quantity, but to give food at short intervals, viz., seven or eight times a day. In this way the stomach is kept busy and the feeling of hunger does not become troublesome, while at the same time the sensation of faintness, which so often is a prominent feature in women, and depends on emptiness of the stomach, is entirely obviated.—*Zeitschrift für Krankenpflege*. July, 1900.

An Unusual Form of Painful Anæsthesia of Hysterical Origin.—Guiseppe Dagnini reports the case of a young woman who exhibited the following symptoms: Total loss of specific sensibility to puncture of the skin and subjacent tissues; loss of cutaneous sensitiveness to thermic and electric stimulation, to space, to recognition of the quality of bodies touching the skin, to the most superficial contact; loss of sense of position of the knee-joint, combined with hyperalgia to the slightest pressure, which became intolerable pain if the pressure were increased. The condition was found to be absolutely of hysterical origin, and was cured by the suggestion that the evacuation of an abscess (due to a hypodermic injection of morphine) done under chloroform, would give relief.—*Rivista Critica di Clinica Medica*, July 7, 14, and 21, 1900.

Five Years' Experience with the Antiseptic Treatment of Typhoid Fever.—J. A. Crook refers to his former communications, in which he showed that carbonate of guaiacol was not taken up from the alimentary canal, but that it passed through as taken in, and hence reached the seat of disease. He believes this drug to be non-irritating to the mucous membrane of the stomach or bowels, and that it may be given in doses sufficiently large to cause disinfection without detriment to the patient. In the past five years the writer has treated one hundred and nine patients, with four deaths. He finds that the strict Woodbridge and Brand methods necessitate worry and annoyance to the patient by the oft-repeated small doses and the too frequent use of the cold bath, when sponging would accomplish what is desired. Intestinal antiseptics are rational and scientific; the course of the disease is shortened, and the mortality is lessened.—*Memphis Medical Monthly*, August, 1900.

Abnormal Electrical Storage in the Human System.—Sir James Grant says that for many years he has been in the habit of treating cases of supposed muscular rheumatism by the insertion of small (No. 8) fine steel needles, the number varying according to the extent of the affected parts, and, as a general rule, the seat of pain will indicate the precise place and extent to which the needles should be used. They remain stuck into the muscles for from one to two minutes. The previous hard, tense condition approximating one of tetany relaxes, the needles are removed without force, and the patient is able at once to use the muscles. Experiments point to an abnormal storage of electricity in the tissues. It may be stored as a result of sudden draughts and cold. When the inserted needles are touched, the electrical accumulation is simultaneously discharged, passing through the body of the operator without any serious result. There is almost immediate relief in lumbago from this acupuncture. Cases are cited.—*Montreal Medical Journal*, July, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 8, 1900.

THE EARLY DIAGNOSIS OF CARCINOMA OF THE STOMACH.

THE prospects of ever attaining comparative success in the surgical treatment of carcinoma of the stomach have come to depend not so much upon surgical skill and technical efficiency as upon early diagnosis, and the term early has now a different significance from what it formerly possessed. At present, if a diagnosis is to be designated early, it must be made very much sooner in the course of the disease than would have been considered early a few years ago, when a diagnosis made before a tumor could be palpated was not looked upon as trustworthy. The surgical side of the question of the treatment of this disease is now in a satisfactory condition as far as technique is concerned, and when it is possible to operate upon patients who are in reasonably good condition the immediate results can fairly be called excellent; but unfortunately very few patients are operated upon in a stage of the disease which, in view of our present knowledge, can be called the most suitable and most promising as to final result.

It is safe to say that the prospects of obtaining a real cure when a tumor is palpable, no matter how movable, are very poor, for there are exceedingly few patients operated on under such circumstances who have survived long enough to be looked upon as safe from recurrence, and, furthermore, we know that patients may reach a very advanced stage of the disease, or may die, without ever having given palpable evidence of a tumor. We certainly cannot use the presence of a tumor as a safe means of diagnosis, if we are seeking information to guide our therapeutics to permanent success. There seems, however, to be hope that we may arrive at a state of knowledge which in many cases will allow us to make a diagnosis of strong probability at least, at a much earlier stage in the disease than heretofore; but to make this possible the clinician is the one who must get the evidence and draw conclusions, and then call upon the surgeon for the performance of an operation which may be only exploratory. We need not always expect to make positive early diagnoses, but we may hope to collect enough evidence from observation and experiment upon which to base a diagnosis of such strong probability that under reasonably favorable circumstances an exploration will often be justifiable and perhaps be followed by a successful operation for radical cure.

In gathering evidence for an early diagnosis, one of the first points to consider is the age of the patient, in reference to which we may say that most cases occur in those who have passed the age of forty-five years, though exceptions to this general rule are frequent enough. Sex does not seem to be of much significance, though if anything the disease occurs oftener in men than in women. A history of chronic gastritis or dyspepsia which does not show signs of amelioration under treatment is always suspicious, and when this condition is associated with a constantly diminished amount of free hydrochloric acid we may make at least a provisional diagnosis of carcinoma of the stomach, and expect by further investigation to disprove or substantiate it. It has been observed that, in connection with the gastritis occurring in the presence of carcinoma, there are certain irregularities in the life-processes of the epithelial cells of the gastric mucous membrane, the so-called atypical and irregular mitoses seen in these cells when they are collected from the stomach washing either with or without the preliminary scraping of the mucous membrane with the end of the stomach tube in order thus to increase the number of dislodged cells. These appearances are practically always demonstrable and occur early in the disease, before the mucous membrane is actually involved in the carcinomatous process, and though perhaps not pathognomonic are certainly of great importance.

The Oppler-Boas bacillus seems to occur regularly in stomachs which are the seat of carcinoma, but, as a rule, too late to influence the making of a really early diagnosis, and the presence of lactic acid has about the same diagnostic value. It does occur in carcinomatous stomachs, but usually too late in the disease to be of assistance in making the kind of diagnosis which will be of much use to the patient. However, the presence of lactic acid and of a tumor, though not early signs, does not necessarily in all cases preclude the possibility of operative cure, though the chances of real cure are much diminished by such signs, in the case of the first because the functions of the stomach must be gravely disordered if it is constantly present in any quantity, and in the case of the second because the disease must have reached very considerable extent if it is possible to feel a tumor through the abdominal walls. Only freely movable tumors need be considered in this connection at all. The discovery of true carcinomatous tissue in the stomach contents undoubtedly makes a diagnosis, but not an early one. A point to remember is that the progress of a case of carcinoma of the stomach will vary according to the site of the growth in the gastric wall and its histological character, so that an early diagnosis in one instance might offer a quite different prospect from what it would in another. Fortunately, the so-called scirrhus type, intrinsically least malignant, is the commonest, and is most frequently located in the pylorus, where it soonest gives symptoms. Hæmatemesis is undoubtedly a symptom of gastric carcinoma, but there are several other conditions which cause vomiting of blood, sometimes in the "coffee-ground" condition, so that at best its presence can afford us only corrobora-

tion, often too late to be of any use, in outlining our treatment. The great aid to early diagnosis is exploratory incision, though even this does not enable us to say positively every time whether carcinoma is present, but it does give us evidence as to whether we are called upon to deal with a lesion amenable to operative treatment, so that what to do next is easily decided. Just when and upon what evidence to make an exploratory incision, and whether to proceed at once with a radical operation, are questions which at present must be answered largely from individual experience and opinion; but the exploratory incision is gaining in favor steadily, and justification for its use is sought in the result of formulating facts such as we have mentioned, in its practical freedom from danger, and in the important knowledge which we gain by it. There is room for a judicious extension of its use.

CHYLOUS ASCITES.

An effusion of fluid into the peritoneal cavity may exhibit a milky appearance from the presence of fat or of chyle. Fatty ascites has been observed in association with tuberculosis or carcinoma of the peritoneum, large numbers of endothelial cells in a state of fatty degeneration being desquamated and partly mixed and partly dissolved in the fluid poured out. Chylous ascites, on the other hand, is dependent upon obstruction to the flow of chyle or rupture of a lacteal, the thoracic duct, or the receptaculum chyli. A case of the latter variety has recently been reported by Croon (*Lancet*, June 23, 1900). The patient was a woman thirty-nine years old, who presented symptoms of carcinoma of the omentum and the mesentery, with resulting ascites. On aspiration three hundred and eighty ounces of fluid resembling pus were removed. This was of pale yellow color, and at first quite homogeneous, but on standing for twenty-four hours a slight creamy layer appeared upon the surface. The fluid had a sweetish, milky odor. It was found to consist partly of finely emulsified fat, but more largely of granular débris, constituted mainly of leucocytes in a state of fatty degeneration. A movable tumor was now found in the region of the gall bladder, and an indefinite, irregular, solid mass in the situation of the greater curvature of the stomach.

Although temporary improvement ensued, the fluid reaccumulated, and after an interval of some three weeks about three hundred and fifty ounces of fluid were additionally removed. Death, however, resulted in the course of a few days. On post-mortem examination, the subpleural lymphatics were found studded with minute carcinomatous nodules. The small intestine was the seat of commencing peritonitis. The mesenteric glands were generally enlarged from malignant infiltration.

A large carcinomatous neoplasm grew from the inner surface of the anterior wall of the stomach, extending from an inch beyond the pylorus for four inches along the lesser curvature. The gall bladder was distended with bile, and the glands and tissues along the larger bile-ducts and in the portal fissure of the liver were extensively infiltrated with new growth. The liver itself contained one small carcinomatous nodule. The small intestine was thickened and contracted throughout its entire length. It contained an immense number of small carcinomatous nodules surrounding and extensively occluding the lacteals, close to the mesenteric attachment. The thoracic duct as well as the receptaculum chyli was healthy, although a mass of infiltrated glands was found lying close beside and pressing on it.

HOSPITAL ABUSE.

That abuse of the privileges intended by hospital authorities only for the worthy poor is not confined to any state or country is amply shown by statements made in an address delivered by Thiery (*Lancet*, July 28, 1900) at the First International Congress on Medical Ethics held recently at Paris. So rapidly is the use of hospitals by those who can afford to pay for medical attention increasing that it has been declared that, in spite of all efforts to the contrary, the time will come when bread and medical aid will be given gratuitously to all who apply, and that the time is not far distant when the medical practitioner will be a paid functionary of the state. The following instances of hospital abuse were cited: That of a jockey who was earning $5,000 a year and went to a hospital to be treated for a sprain; a lady who was able to pay for her journey from America in order to obtain advice at the same hospital; a cashier in a commercial house earning a salary of $4,000; a young lady from Russia who was operated on gratuitously at a hospital and then went for her convalescence on a journey to Italy; a celebrated singer who wanted the hospital surgeon to come to her own house because she did not like to go to the hospital, and who strongly objected to paying any fee whatever. Further, of about fifty thousand births that occur annually in Paris, eighteen thousand take place at public expense. It will thus be seen that, unless the predictions made are to be verified, some steps will be necessary to curtail an abuse that has already attained enormous proportions. The remedy proposed is that clerks or janitors at hospitals should, in addition to taking the names and addresses of patients, make inquiries as to their means of subsistence. An inspector should then institute an investigation for the purpose of verifying the statements made. The very least that can be done under present conditions, is to ask each applicant for gratuitous treatment whether he can afford to pay, and to inform him that the gratuitous services of the hospital and dispensary are only for the worthy poor. The individual should be permitted to decide for himself if he wishes to be made an object of charity.

Typhoid Fever in Newark, N. J.—Numerous cases of typhoid fever occurring among the factory hands in several thread mills have been traced to the use of well-water. Examinations of the water of the wells in the mill yards have shown the presence of typhoid bacilli.

News of the Week.

The Rocky Mountain Inter-State Medical Association.—The second annual meeting of this association was held at Butte, Mont., on Tuesday and Wednesday, August 28th and 29th, under the presidency of Dr. C. K. Cole, of Helena, Mont. There was an interesting programme of papers. A luncheon was had at Columbia Gardens on Tuesday, and the annual banquet at the McDermott Hotel on Wednesday. After the close of the meeting a number of the members joined in an excursion through the National Park.

Yellow Fever in West Africa.—It is reported in Paris that a terrible epidemic of yellow fever is raging in Senegal. Nearly all the French troops, the physicians, the nurses, and others of the civil population have been attacked, and since the rainy season set in the mortality has been about eighty-five per cent. The churches have been closed, and the white troops will be withdrawn at the earliest possible date, their place being taken by native soldiers.

Mortality Statistics of Philadelphia.—For the week ended September 1st there were reported to the Philadelphia bureau of health 413 deaths, 41 more than for the preceding week, and 77 more than for the corresponding week of the previous year. The principal causes of death were as follows: Pulmonary tuberculosis 49, cholera infantum 42, heart disease 35, marasmus 24, pneumonia 19, inflammation of the stomach and bowels 17, nephritis 15, diphtheria 13. Seven deaths were due to sunstroke.

A Ten-Thousand-Dollar Fee.—It is stated that one of the largest fees ever paid for medical services in a single case will be received by Dr. J. N. McCormack of Bowling Green for his attendance upon William Goebel, of Kentucky, after the latter was shot at Frankfort. Arthur Goebel, brother of the dead governor, has accepted a claim against the estate of Governor Goebel for $10.000 for Dr. McCormack's services. It is said that Goebel's life was prolonged by Dr. McCormack until the legislature could meet and elect him governor of the State.

Typhoid Fever in Paris.—The recently published statistics of the health authorities of Paris show that typhoid fever prevails in an almost epidemic form. There were recorded, from the beginning of the year to August 13th, thirty-one hundred and forty-eight cases, of which five hundred and sixty-eight resulted fatally. This is a considerable increase over the records of previous years. Paris is never free from this disease, but until 1898 the number of cases for the corresponding period never exceeded seven hundred. The prevalence and spread of typhoid fever are attributed entirely to bad water. One of the sources from which Paris is furnished is known to be contaminated with the typhoid bacillus, though the water from all the others is comparatively innocuous. The authorities say they are obliged to furnish the bad water with the good owing to the inadequacy of the supply, and the only remedy they suggest is that the inhabitants boil all the water they use, or else drink only natural mineral waters.

Prizes for Charitable Institutions and Health Boards.—The Department of Social Economy at the Paris Exposition embraces a great variety of exhibits, including labor unions, charitable organizations, health boards, department stores, etc. The awards in this section have been announced, and we learn that grand prizes have been bestowed upon the following: Tenement-House Committee, Associated Charities, New York City; State Board of Health, Massachusetts; State Bureau of Charities and Correction, Albany; State Bureau of Charities, Massachusetts; Lunacy Commission, State of New York, Albany; St. John's Guild, New York City; Charity Organization Society, New York City; Association for Improving Condition of the Poor, New York City; and the Children's Aid Society, New York City. Gold medals have been awarded to the New York City Street-Cleaning Department; the Loomis Sanitarium; the Bureaus of Charities of Michigan, California, Illinois, Indiana, Ohio, Pennsylvania, Wisconsin; the Public Charities and Charities Association of Boston; the Lunacy Commission of Massachusetts; the Massachusetts General Hospital, Boston; St. Mary's Hospital for Children, New York City; Johns Hopkins Hospital, Baltimore; Pennsylvania Hospital, Philadelphia; Presbyterian Hospital, New York City; Boston City Hospital, Boston; Hospital for Aged and Married Couples, Boston; Institution for the Assistance of Children, Glenmills, Pa.; Columbia Institution for the Deaf, Washington, D. C.; New York Institution for the Deaf, New York City; Society for the Assistance of Children, Boston; Five Points House of Industry, New York City; Society for Prevention of Cruelty to Children, Brooklyn; State Charities Aid Association, New York City; Mount Sinai Hospital, New York City, and the Association for Improving Condition of Poor, Brooklyn; public baths, New York City. Also to the boards of health of Brookline, Mass., Cambridge, Mass., Chicago, New York City, Philadelphia, Pittsburg, Providence, Boston; and the State boards of health of California, Illinois, Michigan, New York, Pennsylvania, Rhode Island, and Vermont. The following received silver medals: public baths of Boston and Brookline, Mass.; the boards of health of Baltimore, Buffalo, Charleston, N. C., Cincinnati, Cleveland, Detroit, Milwaukee, Minneapolis, Newark, New Orleans, St. Louis, St. Paul, San Francisco, Washington, D. C., Worcester, Mass.; and the State boards of health of Connecticut, Delaware, Florida, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Minnesota, Missouri, New Hampshire, New Jersey, Ohio, Oklahoma, South Carolina, Wisconsin. A bronze medal was given to Dr. W. B. Atkinson.

A Cattle Disease in Eastern Pennsylvania.—An epidemic prevails among the cattle in Monroe and Wayne Counties, Pa., and Sullivan County, N. Y., which is causing the death of large numbers of animals. The chief symptoms are colic, prostration, and petechial hemorrhages on the mucous membranes, followed by death in from a few hours to several days.

Dr. Edwin Klebs, who was for several years professor of pathology in the Rush Medical College and director of the pathological laboratory in the Post-Graduate Medical School of Chicago, has resigned these places and has returned to Germany to reside permanently.

Sanitary Barber Shops.—At a labor meeting on Sunday last it was announced that an agitation for antiseptic barbers' shops is to be started by the walking delegate of the Journeymen Barbers' Union, who is now engaged in a fight to have the Sunday-closing law observed in the barbers' shops.

Congratulations to Major Ross.—The Section of Bacteriology of the International Medical Congress in Paris during its sessions sent a telegram to Major Ronald Ross, of the Liverpool School of Tropical Medicine, extending to him hearty congratulations upon his discoveries regarding the parasitology of malaria.

The Cholera in India.—A despatch from Bombay states that official returns show that there were seventy-nine hundred and sixty-nine deaths from cholera in the native and British states during the week ended August 25th. The number of relief works is decreasing and the numbers receiving gratuitous relief are increasing.

The New Jersey State Board of Health.—Governor Voorhees, of New Jersey, has appointed Mr. George P. Olcott, of East Orange, to succeed the late Dr. Gauntt, of Burlington, as a member of the State board of health. The other members of the board are physicians. It was their wish to have associated with them a sanitary engineer, and Mr. Olcott fulfils this requirement.

The Plague in Glasgow seemed at the beginning of this week to have got beyond the control of the health authorities, but later reports have been less disturbing. One hundred and three suspects were under observation on September 4th, and the disease had spread to Govan, a suburb on the left bank of the Clyde. The number of cases of the disease thus far is sixteen. It has not been officially determined how the disease gained a foothold in the city, but it is not improbable that an efficient quarantine, against which British trade rages so furiously, might have prevented the invasion. Denmark, Belgium, and Austria-Hungary have declared a quarantine against Glasgow, and the port authorities at Liverpool, Southampton, and elsewhere in England have instituted a special medical inspection of vessels from the Clyde. A report was current on Tuesday that two cases of the plague had been discovered in the vicinity of the London Docks. But the medical officer, when questioned on the subject, said he knew nothing about the matter. A case of plague has been officially reported at Buenos Ayres.

A Commission for the Study of Dysentery and Typhoid Fever.—Drs. W. J. R. Simpson, of London, J. Lane Notter, of Netley, and David Bruce, of the British army, have been commissioned by the British government to proceed to South Africa and inquire into the nature, causation, pathology, and modes of prevention (more particularly as affecting armies in the field) of dysentery, and its connection, if any, with typhoid fever. Dr. Simpson is professor of hygiene at King's College, London; Dr. Notter is professor of military hygiene at Netley; and Surgeon-Major Bruce is well known for his discoveries regarding Malta fever and the tsetse-fly disease. It is hoped that something more practical than usually comes from such official investigations will be the result of the labors of this commission.

The Sick and Wounded in China.—A despatch to the surgeon-general from Major Perley, surgeon in charge of the American army hospital at Taku, states that there are one hundred and twenty sick at Pekin and two hundred at Tien-Tsin, many only slightly ill. All the wounded have been brought from the front, and the hospital ship *Relief* will take the more severe cases.

The American Ambulance Corps in China.—A Japanese paper says that "the American ambulance corps has done some excellent work. Their stretchers are the best in the field and show the wonderful inventive faculty of the Americans. The handles of these stretchers are so arranged that they can be formed at once into supports by a clever mechanical contrivance, so that the stretchers can be used as beds or benches for surgical operations. The advantages of this system cannot be too much commended, for on ground so swampy and hot as the soil of Pe-Chi-Li the wounded men cannot safely lie long pending the treatment on the spot; and this inconvenience is removed by the American invention. Sixty men were thus treated directly where they fell, who otherwise would have died. The Japanese medical staff refer to the fact in most praiseworthy terms."

State Hospitals for Consumptives.—No less than twenty-two sites for the proposed hospital for tuberculosis have been inspected by the committee without a decision having been reached as to the most desirable location.

Examination for Senior Assistant Physician at the Government Hospital for the Insane, Washington, D. C.—The United States Civil Service Commission announces that on October 23 and 24, 1900, an examination will be held in any city in the United States where it has a local board of examiners, for the position of assistant physician, senior grade, Government Hospital for the Insane, Washington, D. C. The examination will consist of the subjects mentioned below, which will be weighted as follows: 1, letter writing, 5; 2, anatomy and physiology, 5; 3, general and special pathology, 20; 4, obstetrics and gynæcology, 10; 5, surgery, 10; 6, chemistry, materia medica, and therapeutics, 10; 7, bacteriology and hygiene, 15; 8, mental diseases, 25. It is desired that applicants shall have had at least five years' actual experience in a hospital or institution for treatment of the insane. The age limit is twenty years or over. The salary of the senior physician is $1,200 per annum. This examination is open to all citizens of the United States who are graduates of reputable medical colleges and who comply with the requirements. Per-

sons who desire to compete should apply to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375.

A French Hospital Ship in China.—The French Red Cross Society has decided not to send any ambulances with the French troops to China, and has confined its energies to the equipment and sending out of the hospital ship *Nôtre Dame de Salut*, which left France for China on August 10th. The medical staff of the ship consists of nine surgeons, two apothecaries, and twelve hospital orderlies. Three of the surgeons and ten of the nurses belong to the French navy. The vessel has accommodations for three hundred patients. The amount raised by the Red Cross Society for the equipment and maintenance of the vessel was upward of 1,000,000 francs.

The Clarence Barker Memorial Hospital, which was erected at Biltmore, N. C., in memory of Clarence Barker by his sisters, was formally opened on Tuesday of this week. A fund has been started for a permanent endowment of the hospital.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 1, 1900. August 30th.—Medical Inspector P. M. Rixey commissioned medical inspector from August 24, 1900. Surgeon G. T. Smith commissioned surgeon from August 24, 1900. Passed Assistant Surgeon A. M. D. McCormick detached from the *Chicago* and ordered to the *Montgomery*. Assistant Surgeon J. R. Whiting detached from the *Montgomery* and ordered to the *Chicago*. August 27th.—Passed Assistant Surgeon M. R. Pigott ordered to the Naval Academy immediately. Assistant Surgeon C. A. Crawford detached from the *Chesapeake* and ordered to the *Eagle*. August 30th.—Passed Assistant Surgeon L. W. Spratling detached from the naval hospital, Yokohama, Japan, upon reporting of relief, and ordered to report to the commander-in-chief of the Asiatic station for such duty as may be assigned. Assistant Surgeon F. L. Benton detached from the naval hospital, Cavite, P. I., and ordered to the naval hospital, Yokohama, Japan, for duty.

Mrs. Fannie Lamar Rankin has been chosen as delegate from Georgia to the annual convention of wholesale druggists to meet in Chicago September 15th. This is the second time that she has been selected for this duty.

Promotion for British Acting Assistant Surgeons.—It is announced that the civilian surgeons at present serving with the troops in South Africa are to be offered commissions in the Royal Army Medical Corps, by which means it is hoped to fill some, at any rate, of the numerous vacancies in that discredited service. It is questionable whether the vacancies can be filled even by giving the positions away without examination, and it is certain that the prestige of the service will not be enhanced by introducing possibly unfit men.

Another Great Question Settled.—The International Congress of Animal Protection Societies was held in Paris in July. On the fourth and last day of this congress, July 21st, there was a debate on the subject of vivisection. Almost all the societies represented opposed, to a certain extent, the practice of vivisection, and were willing to vote in favor of restrictive laws tending to diminish and control experiments on living animals. But the antivivisectionist societies were in the majority, and a resolution was passed after an acrimonious debate affirming that "vivisection is a crime, unworthy of the toleration of any people calling themselves civilized." The New York State Antivivisection Society was represented at the congress by a Boston man.

Obituary Notes.—Dr. James Stoughton, surgeon United States navy, was drowned on August 5th in the harbor of Shanghai. He was returning to the United States steamer *Castine* late in the evening, and in stepping into a sampan he slipped and went overboard. A strong ebb tide was running, and he was swept under some junks. The officer with him dived after him, but without success. The body was recovered the following morning, and was buried in the cemetery there.

Dr. Easton Burchard, assistant surgeon United States army, died of dysentery on September 2d on the transport *Grant* at Nagasaki. He was born at Bonnot's Mill, Mo., on March 29, 1865. He was graduated from the Kentucky School of Medicine in Louisville in the class of 1886, and practised for several years in Kansas City. He entered the army as assistant surgeon of the Fifth Missouri Volunteers on May 4, 1898, and was appointed first lieutenant and assistant surgeon in the Fortieth Infantry on August 17, 1899.

Obituary.

WILLIAM SPENCER WARD, M.D.,

NEWARK, N. J.

Dr. William Spencer Ward, who died at the home of his son in Newark on September 1st, was born in Bloomfield, N. J., on July 13, 1821. He was the son of Dr. Eleazar Dodd Ward. The father practised medicine in Bloomfield for a period of fifty years, and his son had been in active practice for nearly the same length of time. He entered Princeton College in 1838, and was graduated in 1841. For five or six years after graduation he was classical and mathematical preceptor in the Bloomfield Academy, and afterward in Montclair. During the latter portion of this time he commenced the study of medicine, with his father as preceptor, and entered the College of Physicians and Surgeons, in New York, in 1847, being graduated from it in the class of 1849. He began his career as a physician in Newark in August of his graduation year, and lived there continuously in active practice up to about two years ago. During the Civil War Dr. Ward was in the government service as an acting surgeon, and was stationed at the Ward General Hospital, in Newark, from 1863 to 1865. He was on the medical staff of St. Michael's Hospital during 1877 and 1878, and from 1881 to 1885 on that of St. Barnabas' Hospital. He was also attending physician to the Protestant Foster Home for over thirty years.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 30, 1900.

The Injurious Effects of Improperly Constructed School Chairs.—J. S. Stone says that lateral curvature of the spine is a disease originating almost always during school life, and is much more frequent among girls than among boys. The ordinary type of lateral curvature is that of the writing position. In Nuremburg twice as many incorrect postures were found among children writing the oblique as among those writing the vertical script, in Munich two and a half times as many, in Fürth and Würzburg four times as many. The chair back has always been the great problem. There are two essentials to a proper back. In the first place, the shoulders should never be forced forward, and in the second, the physiological anterior lumbar curve should be maintained. It has been found a matter of commercial value to provide the typewriter with an adjustable automatic spring back constructed on hygienic principles. Are not the health and well-being of the growing children of the community of as great consequence as the comfort of the typewriters, in whom, because of greater age, deformities are much less likely to occur? No attitude, no matter how good in itself, can be long maintained without fatigue. Professor Mille has devised a chair to allow a change of distance, to allow an upright and a reclining position, and to allow for some changes in the antero-posterior curves of the spine, while at the same time always giving a firm lumbar support.

Results of the Operative Treatment of Cancer of the Breast.—Homer Gage says that although the results are by no means what they ought to and might be, they are sufficient to convince him that in the thorough, complete removal of the cancerous breast we have a means of offering a long immunity from cancerous infection to a large proportion of these patients, and a considerable hope that the immunity may be permanent, a hope which, in the absence of any alternative, is so strong that it certainly ought not to be smothered by a refusal to interfere. To have reduced the mortality to almost nothing, the local recurrences, that is, the external recurrences, from sixty-seven per cent. to less than twenty per cent., and to have increased the number of those who pass the three-year limit free from any recurrence from ten per cent. and fifteen per cent. to more than forty per cent., would seem to be a sufficient justification for the operation. But it must be remembered that these results are to be obtained only by a most thorough and extensive operation, and it is fair to hope that if such an operation can be performed when the growth is discovered early, while the external manifestations are limited to the breast itself, even better results may be expected.

A Case of Parovarian Cyst with Twist of the Pedicle Occurring during the Fourth Month of Pregnancy; Operation; Recovery; Normal Delivery at Term.—By F. B. Lund.

The Surgeon in the Nineteenth Century.—By Frederick Treves.

The Philadelphia Medical Journal, September 1, 1900.

The Etiology of Tropical Dysentery.—Simon Flexner formulates the following conclusions concerning the parasitology of tropical dysentery: (1) No bacterial species yet described as the cause of dysentery has an especial claim to be regarded as the chief micro-organism concerned in the causation of the disease. (2) It is unlikely that any bacterial species that is constantly and normally present in the intestine or in the environs of man, except where the disease prevails in an endemic form, can be regarded as the probable cause of epidemic dysentery. (3) The relations of sporadic to epidemic dysentery are so remote that it is improbable that the two diseases are produced by the same organic cause. (4) The pathogenic action of amœba coli in many cases of tropical, and in certain examples of sporadic, dysentery has not been disproved by the discovery of amœbæ in the normal intestine and in diseases other than dysentery. While amœbæ are commonly present and are concerned in the production of the lesions in subacute and chronic dysentery, they have not thus far been shown to be equally connected with the acute dysenteries even in the tropics. In the former varieties, bacterial association probably has much influence upon the pathogenic powers of the amœbæ.

Differential Diagnosis of Chronic Rheumatism.—J. J. Walsh points out many of the conditions which may be and are confounded with chronic rheumatism. The class to which the name really belongs shows joint lesions which have occurred during an attack of rheumatism and persist even, becoming worse by reason of secondary degenerative processes extending over years. Many others should be called cases of pseudo-chronic rheumatism. Flat-foot, writer's cramp, brachyalgia from carrying loads, umbrellas, and holding up heavy skirts, etc., are forms spoken of. Traumatic neuroses, varicose veins, meralgia paræsthetica, etc., are some of the conditions the writer has found being treated as chronic rheumatism.

The Essential Conditions for Habitation to Develop and Maintain Healthful Family Existence.—Rosa Engelmann makes a plea for the detached suburban home with its wholesome atmosphere as compared with even the model tenement of the city. No parks, public baths, or playgrounds can take the place of the open life out of town. Rapid and cheap transportation is one of the crying problems of the day and should be made a political issue just as much as are sanitary environment, shorter hours of labor, etc. The dwelling-places of the poor of Chicago are described and contrasted with what might be offered outside the city and its slums.

The Relation of Surgery to Diabetes.—C. P. Gildersleeve believes that in aseptic surgery we do not possess the means of preventing gangrene after operations upon diabetic patients, as some authors teach. Cases are cited. The following rules are observed by the writer. (1) He would not operate on any patient suffering from diabetes without first explaining either to the patient or some one in authority the possibilities which might follow. (2) He would refuse to operate on an elderly diabetic subject for any of the simple affections, such as benign tumors, etc., unless there was some special reason for operating, and it is certainly a good rule always to examine the urine in any case of gangrene occurring in elderly people. (3) In the painful, rapidly spreading gangrene which often occurs in these cases, and which is bound to cause death if left alone, he believes in prompt and high amputation. As a rule, he waits until a line of demarcation forms; but in some cases, although the line has not formed, one can judge fairly well about how high it is going by the appearance, and in such a case he would operate before the line had actually formed. Some of these cases are inoperable; there may be complete gangrene of the foot, and the leg may be in good condition. Again, the leg may be indurated and boggy, and this condition may extend as high as the knee or above it, and it would be poor judgment to operate on such a case. Another class of cases is that of dry, comparatively painless gangrene which often affects the toes. These cases will often run their course, the dead parts being cast off, and as a rule they should be left alone, so far as operations are concerned.

The Physiological Training of the Feeble-Minded.—S. J. Fort reviews the history of American institutions and methods. The physiological system as formulated by Seguin is considered, and the kindergarten is thought to be of value. There seems to be no reason to doubt the efficiency of physiological training. The following can be urged for the future. (1) The State owes its mental defectives proper care and training, and a proper consideration of the normal and subnormal demands life-guardianship of those unable to support themselves in the outside world and a bond on the part of the well-to-do that provision shall be made for the support of their feeble-minded progeny. (2) The enormous increase in the number of this class of incompetents urges a closer attention to the proper enumeration of all such defectives in each State.

their registration on the files of State boards of health, and penalizing both parties to a marriage contract in which one is known to be feeble-minded.

Fracture of the Superior Maxilla in a Man Seventy Years Old, with Recovery.—V. A. Latham finds little in the literature relating to the subject, and gives cases with illustrations to show some of the difficulties in treatment and points of interest to the general as well as to the dental surgeon.

A Case of Acute Glaucoma with Sub-Hyaloid Hemorrhage Supervening upon Unilocular Retinitis Albuminurica.—D. Webster and E. S. Thompson report the case of a man aged fifty-six years, who in January of the current year began to have difficulty in seeing with his left eye. He was treated for "cold" without benefit. Three months later his eye began to swell, and an oculist found all the symptoms of acute glaucoma. Myotics failed to give relief, and as the tension of the eyeball threatened permanent loss of sight, iridectomy upward was done under cocaine and suprarenal extract. Immediately after the excision of the iris the whole pupillary area was obscured by blood, which also spread itself over the anterior surface of the iris. He remained in the hospital a period of eighteen days, during which he had treatment with a view to getting rid of the blood in the anterior chamber, but without effect. The hemorrhages were renewed as fast as the blood was absorbed, and the anterior chamber was always from a quarter to half full of blood. His urine was examined and found to be loaded with albumin and with casts of various kinds. His diet was regulated accordingly, and he was treated locally and internally, but still unsuccessfully. Two weeks later, inasmuch as all perception of light was lost, and the eye remained painful and inflamed, enucleation was performed. Some bleeding followed a few hours after the operation, but was controlled by pressure. He was discharged in about ten days with the orbital cavity in good condition and the other eye unaffected.

Fibroid Tumors of the Uterus Complicating Pregnancy.—L. S. McMurtry gives a brief review of this condition, discussing the various problems which it presents. The clinical history is recorded of a case occurring in a woman aged thirty-four years, who gave the evidence of a pregnancy of five months' duration except that the enlargement of the abdomen corresponded to the eighth month. Much difficulty was experienced in emptying the bladder and rectum. Vaginal examination showed the entire pelvic basin to be packed with a hard mass; the cervix could not be felt; the tumor when examined through the abdomen was soft and yielding, almost to the impression of fluctuation; diagnosis, pregnancy with fibromyomata in pelvis, displacing uterus upward. A hysteromyomectomy was done, the mass being amputated from the cervix at the vaginal junction, the cervical stump stitched and dropped, and the peritoneum closed over it and across the pelvic floor by continuous catgut suture. The abdomen was closed in the usual way without drainage. A five-months' fœtus was removed from the uterus. There was an uninterrupted recovery, the patient returning home from the hospital in four weeks.

Atrophic Rhinitis.—J. E. Logan reviews the various theories which have been put forth to explain this condition. He is personally inclined to attach much value to the views of Michel and Grünwald, who attribute to accessory-sinus disease the principal etiological rôle in the affection, especially suppuration of the ethmoid cells. Illustrative cases are given.

The Treatment of Tuberculous and Purulent Joints with Large-Glass-Speculum Drainage and Pure Carbolic Acid: with a Report of Seventy Cases.—By A. M. Phelps.

The Lancet, August 25, 1900.

The Cellular Pathology of To-Day.—J. Burdon-Sanderson says that the word "cellular" has now a wider signification than when it was first introduced into pathological nomenclature, for it comprises not merely histological changes, but the chemical reactions which subsist between the cell and its environment. Formerly we regarded each kind of cell as having a single special function proper to itself, but the progress of investigation has taught us that each species of cell possesses a great variety of chemical functions and that it may act on the medium which it inhabits and be acted upon by it in a variety of ways. Thus, for example, we think of the colorless corpuscles of the blood (or, as we now call them, leucocytes) not merely as agents in the process of suppuration or as typical examples of contractile protoplasm, but rather as living structures possessing chemical functions indispensable to the life of the organism. Similarly we have come to regard the blood disc, which formerly we thought of merely as a carrier of hæmoglobin, as a living cell possessed of chemical susceptibilities which render it the most delicate reagent we can employ for the detection of abnormal conditions in the blood.

Diphtheria in the Horse.—From one case coming under observation, L. Cobbett is led to believe that it is perfectly possible for the horse to suffer from nasal and laryngeal diphtheria. This fact is of importance because it shows another possible channel of contagion to man, and because it has a direct hearing on the origin of antitoxin. It has been shown that the serum of a horse which has never been immunized with the diphtheria bacillus or its products often has the power of neutralizing the diphtheria toxin. The fact that all horses do not possess this natural antitoxin is doubtless to be explained by the fact that it is present only in those who have accidentally contracted the disease.

The Microscopic Appearance of the Motor Ganglion Cells in Five Cases of Peripheral Neuritis.—The exciting cause of the neuritis in the cases reported by W. K. Hunter was alcoholism in four and chronic interstitial nephritis in the fifth, a man who had previously suffered from lead palsy. In general the changes consisted in a granular degeneration with more or less fatty material, giving when faint the impression of a mere yellow stain. In some instances the granular contents of the cells had almost entirely disappeared, leaving the cells "ghost-like," and in many the nucleus was peripheral. Colloid degeneration was frequently present in the coats of the vessels.

Notes on One Hundred Cases of Enteric Fever Treated at the Military Hospital at Naauwpoort, South Africa.—The point of special interest in the article by Derwent Parker is in reference to the value of anti-typhoid inoculation. The general mortality was about ten per cent. It was 2.3 per cent. lower among the inoculated cases than among the cases uninoculated. The average temperature in the first group was nearly a degree lower, but about five and a half days elapsed before it finally became normal. All the inoculations were recent, none being more than six months old.

Furring of the Tongue in Health and Disease.—J. Müller believes that the coated tongue so often observed in perfectly healthy individuals is largely due to excessive proliferation of the hairlike appendages of the filiform papillæ rather than to any extraneous deposit. Some persons have a greater tendency to this overgrowth than others, and it is found less frequently with advancing years. In disease it is not to be regarded as an indication of the condition of the alimentary tract as popularly supposed, though it is nearly always present in acute diseases, whether involving the digestive system or not. In chronic cases it is not nearly so constant, being often absent even in chronic gastritis. On examination of the deposit from a large number of cases it was found that there was no appreciable variation in character in different diseases, and that the average proportions of epithelial cells, bacteria, mould, portions of food, and leucocytes in the mixture were fairly constant. In two diseases, however, viz., pulmonary tuberculosis and gastric carcinoma, the number of leucocytes is uniformly so large as to be a characteristic sign. The causes for the formation of this deposit are numerous. The mechanical element is of importance, for most patients are taking greatly decreased amounts of nourishment or subsisting largely on fluids, so that the normal scouring of the

tongue through mastication and deglutition is interfered with. In many diseases there are increased formation and death of epithelial cells as a result of local congestion and serous infiltration—in fact, a desquamative catarrh which contributes largely to the coating. Changes in the bacterial flora of the mouth, as well as reflex nutritive and vasomotor impulses, also play their part, and, lastly, individual idiosyncrasies and the predisposition to increased growth and size of the filiform papillæ must be taken into account.

The Suture of Arteries (Conclusion).—R. Seggel is of the opinion that in view of improvements in technique and the favorable results obtained in what is now a large number of cases, the ligature of large vessels after injury should not be resorted to until after an attempt at suture has failed. This is especially the case in wounds of the carotids, when, if the artery be tied, everything depends on the almost instant establishment of a collateral circulation, with the result that the death rate is thirty-one per cent., the fatal termination being nearly always referable to the disturbance of the cerebral circulation. It is much wiser to clamp temporarily the vessel above and below, and close the wound by means of fine sutures of silk, or if necessary a portion may be resected and one cut end invaginated into the other according to the method of Murphy. In a case of attempted suicide which involved a good-sized transverse wound of the carotid, the author sutured the artery with three fine silk sutures, piercing the adventitia and media but not touching the intima. The wound was packed and the patient made an uneventful recovery.

Treatment of a Typical Case of Pachydermia Laryngis with Salicylic Acid.—J. Fein reports remarkably good results in the treatment of this refractory condition by means of twenty-per-cent. alcoholic solutions of salicylic acid. In the case cited the immediate relief to the subjective symptoms was very gratifying, and after the treatment had been continued for several months the local appearances had so far approached the normal as to obliterate all the diagnostic features. A year later the patient returned to be treated for another trouble, when it was found that the laryngeal picture was still the same as at the last observation.

A Case of Gastric Carcinoma with Unusual Symptoms, and a Contribution to the Question of Œsophageal Atony.—R. Schütz's patient, a woman aged seventy-five years, gave a history of cachexia and emaciation with dysphagia, and the feeling that food was arrested at the lower end of the œsophagus. During the entire illness no vomiting occurred, and no resistance was offered to the passage of œsophageal bougies. The necropsy revealed a pylorie cancer which had so far invaded the neighboring tissues as to have transformed the stomach into a thick-walled rigid tube about six inches in length, and which was held in a perfectly perpendicular position by peritoneal adhesions. It is to this extensive structural change that the absence of the usual signs of dilatation is to be ascribed, while an increase in the lumen of the œsophagus just above the cardia had undoubtedly served to receive a portion of the food for which there was no room in the very contracted stomach, inducing a secondary atrophy.

A Group of Clinically and Etiologically Related Cases of Chronic Disease of the Upper Air Passages.—E. Neisser and Kahnert report five cases of disease of the upper respiratory passages, of which the most striking feature was the essentially chronic course and the tendency to remissions in summer. In several of these the trouble seemed to be secondary to some acute disease. The mucosa of the entire naso-pharynx, of the pharynx down to and into the larynx, and of the upper portions of the nose is affected, presenting atrophy and swelling of the follicles with a tendency to the copious production of mucus and subsequent desiccation and formation of crusts. Hoarseness and dryness of the throat amounting almost to pain are the principal subjective signs. A bacteriological examination of the secretion revealed the presence of almost pure cultures of organisms resembling diphtheria bacilli in every particular. The blood of the patients was also found to be rich in diphtheria antitoxin.

Is Alcohol a Food or a Poison?—By Kassowitz.

Berliner klinische Wochenschrift, August 13, 1900.

Charcot-Leyden Crystals and Spermin Crystals.—Benno Levy contrasts these two microscopic crystal forms, which are considered identical by many observers. In his opinion they are entirely independent of each other and have nothing in common except a superficial resemblance in form which vanishes on closer study, for then it is seen that they represent different groups, the one belonging to the monoclinic system and the other to the hexagonal. They also differ in their reaction to iodine, which imparts a characteristic violet hue to spermin crystals, but not the Charcot-Leyden form. The former are highly refracting, the latter weakly so, while the Charcot-Leyden crystals have a very important relation to the eosinophile cells which is not observed with the spermin crystals, for, according to the author, whenever the eosinophiles are increased there will also be found Charcot-Leyden crystals, and, on the other hand, the presence of the crystals is always an indication of eosinophilia.

The Stomach Pump as a Peristaltic Stimulant.—Oswald Ziemssen has had recourse to lavage with excellent results in cases of obstinate constipation. Within one-half to one hour it is usual for the procedure to be followed by one or more pultaceous stools, while it frequently happens that after a short course of treatment patients who formerly suffered from the most obstinate constipation have a regular morning movement before the tube is introduced. The cure is usually permanent, no cathartics being required even after years have passed. The operation should be conducted as follows: the tube is introduced into the empty stomach and one to two pints of water are allowed to flow in and quickly siphoned out again, the manœuvre being repeated fifteen or twenty times. The treatment is given every day and the amount of water used increased at each sitting. It is important that the washing be done with a 0.6 per cent. salt solution and not with plain water.

Blood-Pressure Estimations with Gaertner's Tonometer.—By Schüle.

French Journals.

Aspergillosis.—Louis Rénon treats of this affection as a primary disease attacking the lungs, due to the action of the aspergillus fumigatus upon the respiratory tract. He reviews his early work and the confirmation it has received from subsequent observations. At the present time all that is known about the affection as a primary disease can be encompassed in the following conclusions: (1) Aspergillosis is a spontaneous disease common to man and animals. (2) In animals it attacks mammifers and birds; it develops in eggs in incubation and may contaminate the embryos contained in these eggs. (3) In man it develops upon the cornea or the skin, but has its special evolution in the respiratory apparatus, creating pulmonary mycoses resembling tuberculosis and pulmonary gangrene, but without the fetid odor. It may coexist with tuberculosis. Occasionally it is fatal after the formation of cavities in the lungs. It may invade the bronchial apparatus alone, causing membranous bronchitis, of special form and of long evolution. (4) In the etiology and pathogeny of this mycosis, contamination by grain plays a capital rôle, those handling various grains being much more likely to be affected than others. (5) Experimentally in animals the lesions are almost always pseudo-tuberculous, and at times necrotic and ulcerative. (6) Primary aspergillosis is relatively frequent. It is distinctive and absolutely specific.—*Journal des Praticiens*, August 18, 1900.

The Erythemas of Tuberculosis.—Paul Raymond considers it an error at the present day to look upon erythemas as morbid entities. They are only the external evidences of generalized toxic infections. The various infectious processes in which such skin lesions appear are cited, and the latter are regarded as the effect of the products of secretion. In tuberculosis we have all the forms, macular, papular, nodose, and polymorphous. Examples from practice are given. Generalized erythematous lupus is for the writer only the outbreak of persistent tuberculous erythema, as are also plaques of Cazenave's lupus. Transition forms show that erythematous lupus, the persistent erythema of tuberculosis, may be set down against the evanescent forms mentioned. He agrees with Malcolm Morris that lupus erythematosus is an erythema, and should not be classed with cutaneous tuberculosis; it is an erythema of tuberculous essence. Cazenave's lupus should be described as a variety of erythema in tuberculosis and placed in the large class of tuberculous erythrodermias.—*Le Progrès Médical*, August 18, 1900.

Treatment of Hepatic Colic.—A. Mesnard gives a *résumé* of modern treatment, and concludes that the best plan to

pursue is, first of all, to inject morphine from a solution containing atropine, then to cover the painful region with a large hot poultice sprinkled with laudanum, then to give 150 or 200 gm. of anisetted olive oil, or in case of repugnance two soupspoonfuls of pure glycerin. If the crisis is beginning, administer six capsules of amyl-valerianic ether, two at a time at three-hour intervals. If the crisis is established, from time to time a soupspoontul of chloroform water should be given. For persistent vomiting give ice pills, champagne frappé; and as alimentation iced milk, vichy, lemonade with seltzer, cold consommé, all in small and frequent doses. No purgatives should be given and no baths taken during the crisis.—*La Presse Médicale*, August 18, 1900.

American Journal of the Medical Sciences, Sept., 1900.

A Case of Ligature of the Abdominal Aorta Just Below the Diaphragm.—W. W. Keen operated upon a man for ruptured aneurism. The patient survived forty-eight hours. The author gives a *résumé* of all the recorded cases of ligation of the aorta, including one by Tillaux, done since his own. He proposes an instrument for the treatment of aneurisms of the abdominal aorta by temporary compression, and describes one which avoids all danger of pressure on the thoracic duct, and requires only the opening of the abdomen and its application to the vessel. It is possible that the patient might not have to be anæsthetized during the entire sitting. Very possibly, when the aorta has been occluded, the anæsthetic might be withheld and renewed only when the instrument has to be withdrawn. With the modern antiseptic methods he believes it would be possible to retain the instrument in position for two or three days, and reapply the pressure at any time, removing the instrument entirely when the attempt has either been successful or would be best abandoned. The author describes experiments upon animals with the instruments just described.

Idiopathic Dilatation of the Œsophagus.—Max Einhorn by this term means those conditions in which there is dilatation of the œsophagus without any mechanical obstacle within or outside of the œsophageal walls or cardia. He describes ten cases seen by him, and refers to two seen previously. The condition may be the result of paralysis (or atony) of the œsophagus, spasmodic contraction of the cardia, or a lack in the reflex relaxation or opening of the cardia during the act of swallowing. It will be diagnosticated when dysphagia of long standing exists, the swallowing sound is found absent, no organic stricture is encountered, and the œsophagus is found partly filled with unaltered food. Prognosis is good as to life, but bad as regards complete recovery. Treatment should consist of liquid, semi-liquid, and solid foods rich in nutriment. After each meal the patient should perform exercises compressing the chest after deep inspirations for a few minutes; this forces the food down. The œsophagus should be emptied and washed by means of a tube every evening. Bromides, iron, and arsenic may be of benefit.

Myositis Ossificans.—Lydia M. DeWitt reports two cases of this comparatively rare disease. Münchmeyer has described it as a constitutional affection of slow course with periodical exacerbations. There is first infiltration of the intermuscular connective tissue, then a stage of connective-tissue induration, and finally ossification, which begins in the centre of the affected muscle, in the connective-tissue ground substance. The disease usually begins in the neck and back muscles, spreading and producing ever increasing deformity. The etiology is very obscure. Cold, unsanitary surroundings, trauma, and irritation have all been held to be exciting causes, but these are often so slight and trivial that they cannot be sufficient to produce the disease in a normal individual. Virchow believes in an ossifying predisposition in these individuals: others ascribe it to a congenital, not hereditary predisposition. Maunz suggests a disturbance of embryonic development. Brennsohn and others suggest the idea that the disease is due to atavistic influence. The author gives reasons for non-belief in these various hypotheses.

Granular Degeneration of the Erythrocytes, and its Significance in Clinical Pathology.—By Ernst Grawitz.

Sarcoma of the Small Intestine.—By E. Libman.

The Journal of Tropical Medicine, August, 1900.

Cerebro-Spinal Fever on an Emigrant Ship.—C. P. Lucas forwards an extract from a report by the immigration agent-general, dated May 16, 1900. There were six deaths on the ship *Clyde*, due chiefly to cerebro-spinal fever. There was nothing in the weather, so far as the surgeon could see, to cause the disease. There was not the slightest evidence of contagion. There was no relationship or communication between the people affected, and as soon as a case was discovered it was isolated in the hospital, and the place previously occupied disinfected with perchloride solution. There was no sanitary defect on the *Clyde*, which was well ventilated, not overcrowded, and was cleaned and disinfected daily. Treatment in this disease is discouraging. If ice could be had it would do much good, applied to the head. In treating the symptoms bromide of potassium in large doses and morphine hypodermically afford most relief. In reference to the question of ice, in 1880 the surgeon-superintendent of the ship *Allenshaw* expressed the following opinion in connection with an epidemic of cerebro-spinal fever which occurred during a voyage, with a result of ten deaths: "One of the modern small, inexpensive ice machines would probably have saved several lives."

Bilateral Typhoid Gangrene.—M. T. Sarr, writing from Bloemfontein, says that there has been a case in the hospital due to enteric fever. As only eight cases of this disease from this cause are on record, he describes it in full. The patient was a weakly man, aged twenty-three years, whose fever ran a moderate course. Convalescence appeared to be established when he began to be troubled with cold feet. On examination, the right lower extremity was found to be of corpse-like coldness up the junction of the middle and lower third of the thigh, without the slightest pulsation in any part; the left lower extremity was cold as high as the middle of the leg; a feeble pulsation could be felt in the femoral artery down to Scarpa's angle, none in Hunter's canal or below. Operation was out of the question, as it was evident that the blood clot extended far into the right external iliac artery. The patient died about four days after the onset of the gangrene. At the autopsy the right femoral artery was found filled with blood clot, which extended up the external and common iliac to the aorta; the left was filled with clot up to within an inch of Poupart's ligament; no sign of endarteritis could be detected, but the case was evidently thrombosis, not embolism.

A Contribution on the Question of Yaws and Syphilis.—A. B. Duprey holds that yaws is not a form of syphilis, and has nothing in common with it. When calm judgment and a critical professional mind are brought to bear on the subject, there is no reason at all why the malady, however horrible it may appear to the sight, should be thought contagious. Mistakes do occur, especially with papular yaws, but under the lens the papules are seen to be different in appearance from those of syphilis. The author suggests that the cause of yaws, as the disease is known in the West Indies, is the abuse of a mango diet. Arsenic is the drug which answers best in the treatment of this disease.

The Early Diagnosis of Tuberculosis.—S. A. Knopf writes an interesting article under this heading, and discusses briefly the various means at hand for early recognition of the disease. The bacteriological examination of the sputum when it gives positive results is conclusive, but it is precisely in the early cases in which the expectoration is scanty that it is hardest to find the bacilli; the tuberculin reaction is unreliable and not free from risk, the fluoroscope as yet is not able to reveal anything not appreciable to the educated ear, and the latest aid, the agglutination reaction of Arloing and Courmont, gives far too contradictory results to be relied on; so that it is still the physical examination that must bear the crux of the diagnosis. The author considers the various predisposing factors, the points of importance in the history, and finally calls attention to several comparatively little-known physical signs which are of help in making an early diagnosis.

Syphilis and Tuberculosis.—Portucalis draws the following conclusions from an extended period of clinical observation: (1) Syphilis when it is contracted by a phthisical patient arrests the course of the earlier disease. (2) When contracted by a patient already suffering from phthisis, syphilis runs a mild course. (3) The antagonism between the microbes of these two diseases produces a neutralization of their toxins. (4) When the microbe of syphilis has been discovered and its cultivation made possible, we shall be able to prepare a serum with which consumptives may be inoculated and their disease arrested. (5) Inoculation with the blood serum of syphilitics in the third stage would be of great advantage to consumptives.

Education in the Sanatorium.—In Moeller's opinion the beneficial results of sanatorium treatment are entirely due to the summation of many minor curative measures, each of which taken by itself has but slight effect, but combined with others may be productive of greatest good. This

means that the patient must follow implicitly his physician's directions to the minutest detail, and involves a relationship of absolute trust and confidence between the two, to establish which should be the physician's first aim. It is important to keep the patient constantly busy doing nothing, *i.e.*, to occupy all his time without allowing him any definite pursuit which might tend to cause excitement or fatigue.

The Prevention of Infection with Tubercle Bacilli in Schools, the Public Highways, and Railroad Cars (Conclusion).—Mosler's article is a plea for greater care in the disposition of the sputum of consumptives. Experience has shown that this is dangerous only when allowed to desiccate and be diffused through the air as dust, hence adequate provision should be made in all public places for its reception in suitable vessels containing water. Railroads should furnish special cars for the transportation of invalids, and these should not be allowed to make use of the cars in general use.

Preliminary Report upon the Use of Palladium Chloride ($PdCl_2$) Internally in the Treatment of Tuberculosis.—Cohen reports favorably upon the use of this drug, which he was led to investigate on account of its great affinity for hydrogen and its consequent oxidizing and antiseptic power. Patients to whom it was administered for a long period improved in weight, and in a number of cases there was disappearance of the fever and cough with physical signs of active destruction of lung tissue. The dose for an adult is gtt. v.–x. of a three-per-cent. solution, well diluted.

A New Diagnostic Sign in Pulmonary Tuberculosis.—Ferran describes a saprophytic form of the tubercle bacillus which accompanies its growth in the lungs and generates spermin in sufficient quantities to be recognizable by its characteristic odor. Experimenting with this, he has found that it grows best in the serum of sheep at about 37 C. The presence of this odor in cultures made from sputum is sufficient to confirm a diagnosis of pulmonary tuberculosis even if the bacilli themselves cannot be found.

Some Remarks on the Rest and Open-Air Treatment of Consumptives (Conclusion).—Dettweiler sketches briefly the history of the development of the out-door treatment for tuberculous patients, and recapitulates the benefits resulting from it. Properly graduated breathing and gymnastic exercises form an important factor.

The Early Diagnosis of Pulmonary Tuberculosis.—Klynens and Van Bogaert discuss the symptoms and signs of the early stages of the malady and the various other aids to diagnosis, such as the tuberculin reaction, the Roentgen rays, and the serum reaction of Arloing and Courmont.

Tuberculous Gastric Ulcer, with a Case of Chronic Ulcerative Tuberculosis of the Stomach with Fatal Perforation Peritonitis.—By Struppler.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PUBLIC HEALTH—WAR HOSPITALS COMMISSION—THE PRINCE'S CONVALESCENT HOME—ECHOES FROM IPSWICH—DEATHS OF SIR WILLIAM STOKES, DRS. SIMPSON, O'CALLAGHAN, AND ANDERSON.

London, August 24, 1900.

The weather has not settled down since the storms I mentioned, so we did not get a share of your hot wave, but have had some fine warm days with the proverbial thunder to follow. The public health does not seem to have been affected by the unsettled meteorological conditions. The diseases prevalent are those of our summer and their incidence is about the same as the average. The mortality returns include a death from glanders at Guy's Hospital. It is a year since the last death from this cause was registered. A death also is registered from typhus—the first of the kind since February, 1899. Two deaths are also recorded from anæsthetics, making twenty of these fatalities this year. The London death rate has crept up to 20.5; that of the provincial towns is 20.2. The increased rate is largely due to zymotic diseases.

The commission on the war hospitals has arrived in South Africa, and already has begun to take evidence, notes of which reach us by telegraph. Professor Dunlop told them that the soldiers in the Wynberg hospital were as well treated as his own patients in the Glasgow Royal Infirmary. He was perfectly satisfied with the arrangements, but said there was too much red tape. Professor Chiene, who has inspected all the military hospitals during his stay in South Africa, also expressed satisfaction with everything, especially in the Natal hospitals, which were almost perfect. Generally the evidence shows a lack of complaints. Professor Chiene has made a proposal for the creation of an imperial medical reserve, consisting of one thousand surgeons with a due complement of nurses and other officials. He thinks hundreds now in South Africa would be glad to join such a reserve and bind themselves to serve whenever or wherever wanted, without pay.

The invalided officers who are enjoying their sojourn in the convalescent home established at Sandringham by the Prince and Princess of Wales have much to be thankful for. They drive about in the royal wagonettes and dog-carts, play billiards on the prince's table, or repose in comfortable lounge-chairs in the smoking-room. The home was specially established for colonial officers, and before leaving for the continent the prince and princess personally satisfied themselves that every comfort was provided.

The time limit is an important element in considering papers for such assemblies as the British Medical's annual outing. Discussions of a light nature pass off easily enough, but others are apt either to bore or empty the room. A man should not attempt to do more than make a short communication and one that can easily be grasped on hearing it read. Illustrations of this have been given me by those who attended different sections. Thus Dr. Stacey Watson's paper was too long and too intricate to secure proper attention. He had fifteen minutes and required probably forty-five. He had to sit down after furnishing his facts and compressing them into an impossibly small space. In some other papers elaborate statistics were submitted, a consideration of which restricted to a few minutes might perhaps "prove anything."

Much regret and some disgust have been expressed to me at the attack on Professor Cushny's paper by Dr. Barr. It is certain that the professor would not resent fair criticism, but anything like acrimony should be eschewed, especially toward a visitor who had honored the association by his presence and by submitting his paper. Not improbably the paper will receive the more attention when it is published in full.

The report on scientific grants called forth a little criticism as to their distribution. One member moved that these grants be discontinued, and the money be devoted to prizes for work already done. As the motion found no seconder, it may be presumed the meeting was satisfied with the present plan. A distribution of prizes for work done does not offer an ideal method of encouraging research or securing impartiality.

Prof. Walter Smith in presiding over the therapeutical section took the opportunity of denouncing the rubbish advertised among new drugs and preparations, "used chiefly by those who do not know how to employ the old ones." Each new-comer is soon elbowed out by a fresh arrival. He protested against the manner and matter of the advertisements that appear in our journals, and their plausible pretence of original work and offers of "full literature." But these find their way to the waste-paper basket. He further objected to the visits of agents of drug firms as a growing practice "which should be stamped out by the profession." Many will applaud him for this, but more will probably still be ready to receive the canvassers. I do not object to advertisements of drugs in the journals, but there are too many other announcements which degrade our periodicals.

The death of Sir William Stokes was announced on Monday as having taken place on Saturday at Pietermaritzburg. He went out as consulting surgeon to our forces, and was chiefly at work in Natal, where for six months his services have been greatly appreciated. He was one of the most distinguished Dublin surgeons, surgeon to the Queen in Ireland, and has for many years held a leading position. In 1861 he was awarded the gold medal of the Pathological Society and three years later was appointed surgeon to the Meath Hospital. In due time he presided over the society which in earlier days gave him the gold medal. As president of the Dublin College of Surgeons he had a happy time in the Queen's jubilee year, 1887. He was the son of the eminent physician, William Stokes, whose name you will remember in connection with his work on diseases of the chest. Other members of the family have also achieved distinction in medicine, literature, and science. The late Sir William Stokes was professor of surgery at the College of Surgeons, Dublin, for some thirty years. His pupils are scattered over the world, and all will feel on hearing of his death that an able exponent of their art and an upright gentleman has passed away.

Dr. P. A. Simpson, emeritus professor of forensic medicine in Glasgow University, died on the 11th inst., aged sixty-three years.

Surgeon-General D. J. O'Callaghan died on the 12th, aged eighty-five years.

Dr. John Anderson, who died on the 15th, did not practise medicine but devoted himself to natural history. He

was professor in Edinburgh and also in India. He was employed in various scientific expeditions, his report on that to Western China, published in 1871 by the Indian government, being especially valuable. He retired from the Indian service in 1877. He was M.D., LL.D., and F.R.S. Edin., and received various other honors.

LETTER FROM KASHMIR.

(From our Special Correspondent.)

PREVALE DISEASES—SANITARY IMPROVEMENTS — MEDICAL INSTITUTIONS—SURGICAL WORK.

KASHMIR, July 15, 1900.

KASHMIR is on the whole wonderfully free from sickness dependent on climate. Great tracts of the country lie permanently under water and many large areas are exposed to annual floods. During the summer months the valley is little more than an alluvial plain covered with rice fields and swamps. Mosquitos abound; and yet, owing to the altitude, malarial disease is quite rare. The Kashmiris hardly suffer from it at all. Diseases of the eye are, however, very numerous, especially ophthalmia and entropion. Cataract is much less common than in the plains. Diseases of the skin, especially those which are parasitic, simply abound. Scabies, for instance, is universal. Digestive affections are extremely common and are often due to the great excess of starch consumed in a diet which consists so largely of rice. Dilated stomach is of frequent occurrence. In the winter, respiratory complaints, especially bronchitis, abound, and rheumatism is very prevalent. There is a fairly representative series of the general diseases with which we meet in America or Europe. But the variety is more limited, and some affections are conspicuous by their absence, *e.g.*, scarlet fever and diphtheria. Phthisis is comparatively rare and chiefly confined to those, such as shawl weavers, who lead indoor lives, in impure atmosphere. Pneumonia and pleurisy are seldom met with; rickets is rare.

During the recent appalling distress from famine and plague in India, Kashmir has escaped untouched. The cultivation is carried on chiefly by irrigation, and owing to the proximity of the snow mountains the water supply is abundant. Our immunity from plague is partly due to distance. Should the Punjab become generally affected, Kashmir will be in great danger. The filthiness of the city of Grinagar is notorious. Twice recently we have been visited by epidemics of cholera, viz., in 1888 and 1892. Each time the mortality exceeded ten thousand. The soil of the city and in the villages is sodden with the accumulated filth of ages, to which fresh additions are being made daily. Enteric fever is very common.

After the last cholera epidemic a most important sanitary improvement was effected in the introduction of a new and abundant supply of pure water, brought in pipes from a neighboring mountain stream. Among other improvements may be mentioned the construction of a large number of public latrines, a systematic attempt to remove filth from the city, the levelling and metalling of many roads, and efforts to control cow-houses, slaughter-houses, and offensive trades. An attempt has been made to do systematic vaccination. A good deal has been done, but more efficient control of the public vaccinators and of the calf-lymph stations is urgently required.

There are five medical institutions in Kashmir. Of these, the oldest is the Kashmir Mission Hospital. This contains one hundred and twenty beds and draws patients not only from the valley of Kashmir but from all the districts around, Poonch, Kishtiwar, Ladakh, and Baltistan. The total number of out-patient visits last year was 41,628. The state leper hospital with ninety beds is also under the superintendence of the mission surgeons. The other three hospitals are the state hospital, the Diamond Jubilee hospital for women, and a small hospital for the foreign community. In several of the larger towns and villages there are state dispensaries.

It is astonishing to how large an extent out-patient practice in Kashmir is surgical. And the proportion of surgical patients requiring operative treatment is equally surprising. Last year, in the Kashmir mission hospital 4,148 operations were performed. Of these 856 were for entropion, 240 for pterygium, 93 for cataract, and 250 for bone disease; 304 tumors were excised (including 2 ovariotomies). There were 29 cases of epitheliomata of the thigh and 15 of the abdominal wall. Those which are due to burns and subsequent irritation from the heat of the portable brazier (kangri), which the people carry under their clothes in the winter, are in the early stages absolutely curable. They are often of slow growth, but sooner or later the lymph glands become affected. The case then assumes a much more serious aspect. The immediate risk from operation is small (of more than three hundred operations for epithelioma performed by Drs. Arthur and Ernest Neve since 1890, only one proved fatal). Experience has shown that it is inadvisable to do very sweeping operations when the glands are extensively involved or the skin over them is brawny.

A very cheap dressing is used in the Mission Hospital, consisting of muslin bags of various shapes and sizes filled with cedar sawdust. Before use these are sterilized by heat. Usually a deep dressing of Lister's double cyanide gauze is placed underneath each bag. The economy effected in a large hospital by the use of these bags instead of expensive medicated cotton wool is astonishing.

THE SOLDIER IN THE TROPICS.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: Not long ago I had the privilege of stating in your columns my views regarding the acclimation of the white man in the tropics. I adhere to what I said and indorse every word uttered by Capt. Charles E. Woodruff, M.D., in a recent paper on "Medicine in the Tropics." It is true that the white man can live in the tropics if he is able to surround himself with many precautions; but that is not the kind of life characteristic of the white man and expected of him; that is, not being acclimated, he vegetates and his offspring will be degenerates. If that is true of the white man in general and of the colonist especially, it is much more true, and necessarily so, of the soldier, whose calling imposes on him extraordinary hardships and exertions; and there will always be a great distinction to be made between the soldier in garrison and in campaign. The three points to be considered in making life possible in the tropics are feeding, clothing, and housing.

About housing not much need be said. In garrison suitable barracks will be provided for, and in campaign the soldier must take it as it is. Tents will be quite necessary.

With regard to clothing I wish to say that cases of sunstroke are of rare occurrence among the people of tropical countries, because they are not foolish enough to walk in the hot sunshine, to use tight clothing, to wear heavy covering for the head, or to carry weights which oppress the chest. The commanders of troops are responsible for neglect of these points. We all know that soldiers, when they have to march or to fight in the hot sunshine, gradually throw away everything that oppresses them, such as knapsacks and coats; and they would soon throw off their caps or helmets if they were able to get straw hats instead. The tropical helmet may be very good, but I think that straw hats would be most welcome to the soldier in campaign during the hot season or in hot countries. There must come a day when the question will be not so much how pretty the soldier looks as how he feels and how far he is able to do his duty. Heat weakens man by excessive perspiration, loss of appetite, and loss of sleep; but it is my belief that the most dangerous hours of the day in the tropics are not the hottest ones, but the early hours in the morning before the sun rises, when the air is often decidedly chilly. How many Mexicans have I seen travelling without any other protection against the lower morning temperature than a silk handkerchief wrapped round the neck! Abdominal bandages are not necessary, and the men will soon throw them away.

Finally comes the most important item of feeding. Lately there has been much said and written on this subject, and a "soldier's ideal ration" has been invented and, I am told, has already proven a failure. Suppose now that the home ration of the United States soldier were all right, when the troops are sent to the tropics some change may be convenient in regard to quality, not to quantity. If the soldier is furnished something he will not eat and is expected to sell part of it and buy something he will eat, that is not the so-called "ideal ration." Besides, even if that expedient is admissible in garrison, it becomes at once impossible in campaign.

The soldier in the tropics ought to have more fat than at home, perhaps a trifle less meat, and some alcohol. So far as the latter is concerned, I should prefer wine to whiskey, and much more so if the men can be prevailed upon to take their share of wine mixed half and half with water. It is shocking to all foreigners to see what quantities of fat Mexicans eat with their meals.

For the soldier in campaign we cannot rely upon fresh provisions. We must furnish the men with food easily transportable, not too voluminous, palatable, and quickly made eatable. If the men are tired, they will do as the horses do—drink and lie down and sleep rather than eat or wait for their food to be cooked.

We must, to a certain extent, rely on canned things. The use of canned beef is necessarily limited, as the men soon get tired of it, and salt dry pork or beef will be found

more acceptable. I wonder why dry cheese is not more extensively used, if it is true that 272 gm. of cheese are equivalent to 118 gm. of albumen, and if 1,160 gm. of cheese represent 318 gm. of carbon! I believe that for expeditions of a few days soldiers will be satisfied if they get ham, cheese, hardtack, some alcohol, and coffee.

Now, as to quantities. A man who is doing heavy work, such as a soldier during a campaign, ought to have somewhat more than when he is at home and in garrison. The white soldier in the tropics, as long as he is in good health, will not eat noticeably less than he does in his native country. The war ratio required for the German troops in France was: Bread 750 gm., meat 500 gm., bacon 250 gm., coffee 30 gm., tobacco 60 gm. (or five cigars), wine 500 gm. (or beer 1,000 gm., or brandy 200 gm.). DR. SEMELEDER.

CORDOBA, STATE OF VERA CRUZ, MEXICO,
August, 1900.

EXTERNAL ABDOMINAL EXAMINATIONS DURING PREGNANCY AND LABOR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I notice in the very interesting "Address in Obstetrics," by Dr. William F. Smyly, delivered before the British Medical Association at its recent meeting, and reported in the MEDICAL RECORD for August 25, on page 310, a statement which I consider unjust and to which I desire to take exception.

The report says: "Next to antiseptics, the author considered the substitution of external for internal examinations the most important advance in modern midwifery. By whom it was introduced he did not know, but its systematization and popularity were owed to Pinard, Credé, and Leopold"; and then the report goes on to give the now well-known advantages and uses of external abdominal manipulations and examinations during pregnancy and labor.

Now, Mr. Editor, I do not care so much for the point of original priority in this matter, for I personally have no such claim to make regarding the discovery and systematization of this most beneficent method of obstetric practice. But I do protest against being left "out in the cold," together with several other colleagues and contemporaries, when the question of having contributed to the "popularity" of the method is considered. Who originated the practice of determining the position of the child in utero by external (abdominal) examinations, I do not know; that it did not originate with Pinard, Credé, or Leopold is, however, certain. Wigand, d'Outrepont, and Busch (all Germans) were generally credited with having first introdnced external version into obstetrics; Braxton Hicks and Wright certainly originated "bipolar" version; Credé undoubtedly devised his method of expressing the placenta. But neither Pinard nor Leopold, so far as I know, contributed anything original or new to these methods; nor did I, Mr. Editor.

But these methods were well known and universally practised and taught in all the maternity hospitals and obstetric clinics in Germany when I became assistant to Professor von Scanzoni, at Würzburg, in 1867, then the greatest authority on obstetrics and gynæcology in Germany. For three years I taught these methods to the students at Würzburg, and no pregnant or parturient woman was ever examined per vaginam in those days until the usual routine external exploration had been made; and so much was I impressed by the simplicity, utility, and safety of this practice that, while in Vienna in the winter of 1871 to 1872, I began to write a paper on the subject for publication in America, where I knew the method was not understood, appreciated, or practised. This paper was not finished at the time, as I left Vienna and travelled for about a year; and in the mean while my friends, Drs. William L. Richardson and James R. Chadwick, of Boston, who had first seen and learned the method in Vienna in 1871, each wrote a short article on it, and, if I remember correctly, a Louisville physician also, whose name I do not recollect—all about the same time. Reminded by these articles of my unfinished paper, I at once resumed work on it, and published it in *The American Journal of Obstetrics* for July and August, 1879, and April, 1880, under the title of "Obstetric Palpation: the Diagnosis and Treatment of Obstetric Cases by External (Abdominal) Examination and Manipulation," from which it was reprinted as a bound monograph of about one hundred and twenty pages, with illustrations. Unfortunately, the edition was small, only one hundred copies, and was soon exhausted, but even up to within a few years there have been calls for it.

Pinard's very elaborate work on the same subject appeared almost simultaneously with mine, although mine was begun seven years earlier. To Leopold belongs the credit of having in recent years emphasized the possibility of avoiding vaginal infection by a thorough carrying out of abdominal examination of pregnant and parturient women to the large exclusion of vaginal touch, certainly a great merit, but in no wise original.

But to Richardson, Chadwick, and myself, I think, belongs the credit of having first written up and popularized the method of external examination of pregnant and parturient women for an English-speaking public, and of these articles mine alone can lay claim to completeness, as it was exhaustive and covered the whole subject, while the others were only short papers. Of course, I do not impute to Dr. Smyly any intention in omitting our names, and I am sure he would gladly rectify the omission were it still in his power to do so. I trust, Mr. Editor, that you will pardon my transgressing so greatly on your valuable space for a personal matter. PAUL F. MUNDÉ, M.D.

HOTEL NEW FRONTENAC, THOUSAND ISLANDS,
August 27, 1900.

Reviews and Notices.

A MANUAL OF OBSTETRICS. By A. F. A. KING, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Columbian University, Washington, D. C., and in the University of Vermont, etc. Eighth edition, revised and enlarged. With 264 illustrations. Philadelphia and New York: Lea Brothers & Co. 1900.

IT is only two years since the appearance of the seventh edition of King's Manual. The best recommendation any work can have is the rapid exhaustion of its edition. And when a work has been before the public for nearly twenty years, and this rapid exhanstion still continues, nothing further need be said as to the quality of the book. Materially enlarged in every direction, it can contrast with any of the larger standard works. We have no criticism to offer and no major corrections to be made but one; and that is a false interpretation of the Walcher position so far as the plate showing this posture is concerned. The plate is faulty in so far as the patient is not carried sufficiently over the edge of the table. We thank the author for his painstaking revision of his work.

A MANUAL OF OBSTETRICAL TECHNIQUE, AS APPLIED TO PRIVATE PRACTICE: with a Chapter on Abortion, Premature Labor, and Curettage. By JOSEPH BROWN COOKE, M.D., New York, Late Attending Physician St. Mary's Free Hospital for Children, Out-Door Department; Late Attending Physician Northwestern Dispensary, Department of Diseases of Children; etc. Philadelphia and London: J. B. Lippincott Company. 1900.

THE little volume before us can be recommended to the student during his first year's course as well as to the midwife, but it is certainly not a book for the practitioner. It cannot compare with the many we have had the pleasure to review. The plates are good, but many are unnecessary.

GUIDE PRATIQUE D'ÉLECTROTHÉRAPIE GYNÉCOLOGIQUE. Par LE DR. E. ALBERT-WEIL, Licencié ès-Sciences Physiques et Chimiques, Ancien Interne de Saint-Lazare, Préparateur Adjoint à la Faculté de Médecine de Paris, Médecin-Electricien. Paris: B. Baillière et Fils. 1900.

IN the tendency to resurrect electro-gynæcology at the present time, we welcome this work, though small in size, as a useful appendix to the larger and older works. The pictures explain very thoroughly what the text fails to make quite clear. It makes very pleasant reading, and no more profitable hour could be spent than in its pernsal.

CHIRURGIE DU REIN ET DE L'URETÉRE. Par V. ROCHET, Chirurgien de l'Antiquaille, etc. Paris: G. Steinheil. 1900.

THIS is a useful and systematically arranged little volume on the subject of the surgical diseases of the kidneys and ureters, and the treatment of these conditions. There are an introductory chapter upon the anatomy of the urinary organs, and then a series of chapters containing descriptions of the pathological conditions which are met with in them, with detailed accounts of the various forms of treatment. There are enough statistical and bibliographical references to give the book considerable value as a work of reference, and some useful explanatory illustrations.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1899. Vol. XVI. Edited by M. C. O'BRIEN, M.D. Published by the Association.

THE volume opens with the address of welcome by Frederick W. Wiggin, chairman, followed by the address of

the president, Joseph D. Bryant. About sixty papers fill the greater part of the remainder of nearly nine hundred pages, neatly bound to match former reports. A very valuable feature is the alphabetically arranged comments on the materia medica, pharmacy, and therapeutics of the year, prepared by E. H. Squibb, Jr. It takes in over two hundred of the 887 pages contained in the whole report.

Essentials of Medical and Clinical Chemistry, with Laboratory Exercises, by Samuel E. Woody, A.M., M.D. Fourth edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. 1900.

This little work has long been regarded as one of the best of our text-books on medical chemistry, and it has lost none of its value in the present revision. The author states that it has been largely rewritten and much new matter has been added. The laboratory exercises are inserted as foot-notes. There are seventy-six illustrations.

Golden Rules of Ophthalmic Practice. By Gustavus Hartridge, F.R.C.S., Senior Surgeon Royal Westminster Ophthalmic Hospital; Ophthalmic Surgeon and Lecturer on Ophthalmology, Westminster Hospital. "Golden Rules" Series No. VII. John Wright & Co., Bristol; Simpkin, Marshall Hamilton, Kent & Co., Limited, publishers, London.

This book is about two by three inches in size and contains sixty-nine pages. There are a few paragraphs descriptive of the physiological and pathological conditions of the eye, and some short, pithy admonitions regarding the treatment of ophthalmic cases.

Original Contributions Concerning the Glandular Structures Appertaining to the Human Eye and its Appendages. By Adolf Alt, M.D., Professor of Ophthalmology in Beaumont Hospital Medical College, St. Louis. St. Louis American Journal of Ophthalmology, Publisher. 1900.

This monograph is a most valuable anatomical study of the glands of the orbit, lids, and conjunctiva. It contains only twenty-three pages of text, but is illustrated by thirty-six excellent plates made from photographs taken by the author.

Encyklopædie der Therapie. Herausgegeben von Oscar Liebreich, Dr. Med., Geheimer Medicinalrath, o. ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universität. Unter Mitwirkung von Martin Mendelsohn, Dr. Med., Universitäts-Professor, Priv.-Doc. der Inneren Medicin an der Friedrich-Wilhelms-Universität, und Arthur Würzburg, Dr. Med., Kgl. Sanitätsrath, Bibliothekar im Kaiserlichen Gesundheitsamte. Berlin: August Hirschwald. 1900.

This, the third fasciculus of the third volume, completes the excellent encyclopedia of therapeutics, the appearance of the successive parts of which we have noted from time to time in these columns. This number carries the titles from Secale Cornutum to Zymotische Krankheiten, and includes such important subjects as medicinal soaps, septicæmia, scirrhus, spectrum analysis, sputum, sterility, metabolism, strychnine, syphilis, tetanus, inebriety, uræmia, mastoid disease, water, childbirth, and teeth. An index, which is wonderfully complete for a foreign book, adds greatly to the value of the work, especially for a non-German reader who is sometimes at a loss for the German name of a disease and who can find it in the index under its Latin name.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., F.R.S., etc., and F. F. Burghard, M.D., and M.S. (Lond.), F.R.C.S., etc. In seven volumes. Volume III.: The Treatment of the Surgical Affections of the Bones. Amputations. Philadelphia and New York: Lea Brothers & Co. 1900.

We have before us now the third volume of this excellent work, and we might say here that we should be glad to have the remaining four volumes appear at shorter intervals than has so far been the case with the first three. This section contains the subject of fractures and their treatment, and descriptions of the surgical diseases of the bones. As in the previous instalments of the work, it has been the aim of the authors to limit themselves in the discussion of treatment to what they consider best and most suitable, leaving many methods merely mentioned or ignored entirely. This method has made possible a conciseness and practicalness which could not otherwise have been attained, and has obviated much prolixity. The treatment of compound fractures is considered in an excellent chapter, and minute directions are given for securing asepsis at the site of the injury. The authors are believers in the use of silver wire for maintaining apposition of fragments both in compound and in some forms of simple fracture, notably of the patella, in which condition they believe that operation is indicated unless some reason exists for the avoidance of any kind of operative intervention. The objections to the use of silver wire, in the patella especially, are recognized, but the good points of catgut are not mentioned. Tumors of bone do not receive perhaps quite all the attention which the importance of the subject seems to demand, but the subjects of inflammation of various kinds in bone, and its sequelæ, are well covered. There are many illustrations showing the methods of treating different forms of fracture. The last part of the book is devoted to the subject of amputations, and here, too, the illustrations are very good. Descriptions of useless and obsolete methods have been omitted, and some space has been given to a satisfactory discussion of the general considerations of amputations. Lister's tourniquet and Davy's lever are, we think, wisely condemned in disarticulations at the hip.

Diseases of the Chest, Throat, and Nasal Cavities. By E. Fletcher Ingals, A.M., M.D. Fourth Edition. Illustrated by 254 Cuts and a Plate in Colors. New York. William Wood and Company. 1900.

This work possesses a distinct advantage over most treatises on diseases of the nose and throat in that it treats of bronchial, pulmonary, and cardiac affections as well, embracing therefore the diseases of the entire respiratory tract together with the mutually dependent heart troubles. The book is doubtless familiar in one of its earlier editions, but the present edition surpasses the others in that it has been brought fully up to date, much important matter, especially regarding pulmonary affections, having been added. Dr. Ingals has a clear style, and his descriptions are to the point and not too verbose, yet sufficiently full to meet the needs even of the student. The illustrations are good and sufficiently numerous.

Atlas and Epitome of Diseases Caused by Accidents. By Dr. E. Golebiewski, of Berlin. Authorized Translation with Editorial Notes and Additions by Pearce Bailey, M.D., Neurologist to St. Luke's Hospital, etc., New York. Philadelphia: W. B. Saunders & Co. 1900.

This volume is upon an important and only recently systematized subject, which is growing in extent all the time. Accidents are coming to form such a considerable proportion of the causes of human ills that the study of their effects is almost a separate specialty, and the Germans have invented a special term for it, "Unfallheilkunde." This book contains much useful information upon the nature and effects of various forms of accidental injury, and upon percentages of disability as estimated under German law. It ought to be useful as a guide to our own examining physicians and adjusters. The work of the translator and of the editor has been carefully done, and the pictorial part of the book is very satisfactory.

A Text-Book of Practical Medicine. By William Gilman Thompson, M.D., Professor of Medicine in the Cornell University Medical College, New York City; Physician to the Presbyterian and Bellevue Hospitals, New York. Illustrated with Seventy-nine Engravings. New York and Philadelphia: Lea Brothers & Co. 1900.

The first thought that comes to the mind, as one sees the announcement of a new text-book of general medicine, is: "What's the use of another?" But the answer to this depends largely upon the authorship of the new work. When the writer is one of the ripe experience in practice and in teaching and of the scholarly attainments of Dr. Thompson, then there can be no question of the utility of issuing the work. Every man has some special knowledge of his own, acquired through observation and not from books, and he does a service to his fellows when he shares this knowledge with the world and so adds to the sum of general information. For this reason Dr. Thompson's book is welcome. The weak point in the book is one on which, curiously enough, the author lays special stress in his preface, and that is the treatment of disease. In this department, so far as the reviewer has been able to discover after a pretty careful search, there is little or nothing that is not already the common property of the medical profession, and many methods vouched for as more or less efficacious by competent and trustworthy observers are utterly ignored. For example, nothing is said of Baccelli's treatment of tetanus, of warm baths in the treatment of cerebrospinal fever, of the salicylates and of sudation in pneumonia, or of the so-called eliminative treatment of typhoid fever, and the section on the treatment of neuralgia is brief and unsatisfactory. In other places, however, it is only fair to say that the therapeutic recommendations are excellent. The descriptions of the individual diseases are clear and concise, and the value of the work is greatly enhanced by the incorporation of the results of the author's experiments and studies in his hospital and private practice. The work, even with the drawbacks mentioned, is a welcome addition to our literature and reflects credit upon American medicine.

Therapeutic Hints.

Intestinal Meteorism in Infants.—

℞ Sodii sulpho-carbolat..... 0.25–0.50 cgm.
Syr. aurantii cort amar..... 5 gm.
Aq. menth. pip. dest..... 25 "
M. S. Take a teaspoonful three times a day for two consecutive days.

—Freyberger.

Painful Pharyngitis.—

℞ Morph. sulphat..... 0.20 cgm.
Acidi carbol.,
Tannin.....āā 2 gm.
Glycerin.,
Aq. destil.....āā 15 "
M. S. Apply to the throat.

—Fletcher Ingals.

Chloroanæmia.—

℞ Artemisine..... 0.001 mgm.
Quassine (crystal.)..... 0.001 "
Ferri protoxalat..... 0.10 cgm.
M. One capsule. S. Two twice a day before eating.

—*Le Progrès Médical*, August 11, 1900.

Rosacea.—Apply with a brush for three days; after the paint peels off about the sixth day, reapply:

℞ Resorcin..... 1
Ichthyol..... 2
Collod. flex..... 30

—Petrini and Galsaz.

Conjunctivitis (simple catarrhal).—

℞ Ac. boric..... gr. xl.
Sodii chl..... gr. vi.
Aq. camphor.,
Aq. destil.....āā ʒ ij.
M. S. Apply every two hours.

—*Can. Pract. and Rev.*

Endometritis (chronic).—

℞ Solutio iodi (Lugol) fort..... ʒ iij.
Ac. carbol. (crystal.)..... ʒ i.
Glycerini..... ʒ iv.
M. S. Apply through the cervical canal.

—Spangler.

Chronic Coryza in Infants.—

℞ Bismuth. salicylic.,
Bismuth. benzoat.....āā 4.
Sodii benzoat..... 1.50
Orthoform..... 0.50
Menthol..... 0.50
Talci..... 10.
M. S. Insufflation.

—*Le Progrès Médical*, July 14th.

Terpin Mixture.—

℞ Elix. terpin.,
Terpin.....āā 20
Spt. vini rect. (ninety per cent.)..... 300
Glycerin. (thirty per cent.)..... 670
Tinct. vanillæ..... 10
Dissolve the terpin in alcohol. Add the tincture of vanilla and then the glycerin.

—*Journal des Praticiens*, July 28, 1900.

Hay Fever.—To ward off or to mitigate the attack in rheumatic patients:

℞ Brucinæ phosphat..... gr. iij.
Ext. hyoscyami..... gr. xv.
Quininæ valerianat..... ʒ i.
Camphoræ..... gr. xxx.
M. ft. caps No. xxx. S. One four times a day.

Tablet pulv. adrenals (desiccated).....āā gr. v.
No. xxiv. S. One dissolved in the mouth four times a day.

This gives great relief during the attack.—Solis-Cohen.

Craving for Whiskey is overcome by dropping a few drops of tincture of cinchona far back on the tongue.

Itching Conjunctivæ in hay fever, etc.—

℞ Sodii biborat..... gr. viiss.
Aquæ camphoræ..... ℥ i.
M. S. Bathe the eyes as necessary, and drop in one or two drops several times daily.

Teething Powder.—

℞ Calomel..... ʒ i.
Carmine..... gr. x.
Sugar..... ʒ iv.
Sugar of milk..... ʒ iij.
M. S. From three to six months of age, gr. vi.; from six to twelve months, gr. viii.; from one to three years, gr. x.

Dipsomania.—

℞ Apomorphinæ..... gr. iij.
Tr. calumbæ..... ʒ i.
Tr. capsici..... ♏ xv.
Tr. nuc. vom..... ʒ i.
Tr. cinch. comp..... ʒ iss.
M. S. Small teaspoonful after meals in water.

—*Cronica Medica.*

Bronchitis.—

℞ Terpinol.,
Sodii benzoat.....āā gr. ij.
Sacch. lact..... q.s.
For one pill. S. From six to twelve daily.

—*The Med. Times and Hosp. Gaz.*, July 4, 1900.

Seasickness.—Codeine gr. ¼ in an effervescing mixture. Useful in vomiting from any cause.

℞ Menthol..... 0.1
Cocaine..... 0.15
Syr. simp..... 30.
Spir. vini rect..... 60.
M. S. Teaspoonful every half-hour.

Neurasthenic Headache.—

℞ Zinci valerianat.,
Ferri sulphat.,
Ext. rhei,
Asafœtidæ.....āā gr. xviij.
M. ft. pil. No. xx. S. One t.i.d.

Strychnine in large dose after hemiplegia increases blood pressure and may lead to second rupture of the weakened artery. It is likewise contraindicated in all forms of hemiplegia, and tabes.—*Medicine.*

Digitalis is unsatisfactory and uncertain because its action cannot be controlled. Strophanthus is greatly superior, being more prompt and more permanent.—Upshur.

Freckles.—Lactic acid and glycerin in equal parts.

Butter in considerable quantities added to the food is the best means of preventing constipation in infants.—Doerfler.

As a substitute for cod-liver oil in the treatment of children's diseases.—Wirschillo.

Substitute for the Poultice.—

℞ Kaolin..... 1,000 parts.
Glycerin..... 1,000 "
Ac. boric..... 100 "
Ol. menth. pip..... 1 "
Ol. gaultheriæ..... 1 "
Ol. eucalypti..... 2 "

Heat the kaolin to 212° F. for an hour to make sterile. Add the glycerin and heat for forty minutes. Stir in other ingredients and keep in air-tight jars.—Wilbert.

Ozæna of atrophic rhinitis. Cleanse with an alkaline solution, then with peroxide, and again with the alkaline wash. Apply by insufflation:

℞ Ac. citric..... 75 parts.
Sacch. lactis..... 25 "

—Somers.

Trifacial Neuralgia.—Introduce into the external auditory meatus pledgets of cotton soaked in chloroform and covered with dry cotton wool before insertion.—Bose.

Craving for Morphine or Spirits.—

℞ Ammon. bromidi ..... gr. v.
Ext. bellad. fld.,
Ext. nuc. vom. fld.,
Ext. cannabis ind. fld ..... āā ♏ ij.
Aquæ ..... ad ℥ ij.
At dose four times a day.

—L. V. Weathers.

Parenchymatous Nephritis (chronic).—

℞ Tinct. cantharid ..... ♏ xxiv.
Liq. ferri et ammon. acetat. ....q s. ad ℥ iij.
M. S. Teaspoonful every four hours.

—Salinger.

Stop Coughing by taking in a long breath and holding it as long as possible. The procedure is said to have a soothing effect on the air cells.—*Virginia Medical Semi-Monthly.*

Chancroid.—Cleanse with

℞ Ac. boric. 1
Aquæ 30
Spir. vini rect 60

Apply for twenty-four hours:

℞ Zinci chl. 1
Zinci oxid 10
Aquæ dest ..... q.s.
Ut ft. pasta.

—Hallopeau and Lerrede.

Tremor of paralysis agitans is notably diminished by one or two injections daily of hydrobromate of hyoscine gr. $\frac{1}{200}$.—Erb.

Threatened Uræmia.—To stimulate cutaneous perspiration in Bright's disease:

℞ Pilocarpin. hydrochlor. ..... 0.01 cgm.
Muc. gum. acac. ..... 100. gm.
M. S. From three to six dessertspoonfuls daily.

This small dose acts without causing the inconveniences of larger quantities of pilocarpine.—Lemoine.

Creosote Pills.—

℞ Beechwood creosote ..... 30 gm.
Ol. amygd. dulc. ..... 10 "
Axungiæ ..... 10 "
Magnes. calcin. lev. ..... 10 "

Mix together the creosote and oil, add the axungia in a mortar and then the magnesia. Stir occasionally during the next twenty-four hours and put into a receptacle.—Delestrac.

Ovarian Neuralgia.—

℞ Ext. bellad. ..... 0.25 cgm.
Ext. stramonii ..... 0.30 "
Lactophenin ..... 6. gm.
M. div. in pil. xx. S. Two or three daily.

—C. S. Martin.

Addison's Disease.—Suprarenal extract in dose of gr. ix. produced rapid improvement in a case. In forty-three collected cases so treated there was improvement in thirteen, recovery in nine, death in eleven; no improvement in three, and in seven the result is not recorded.—W. W. Johnston.

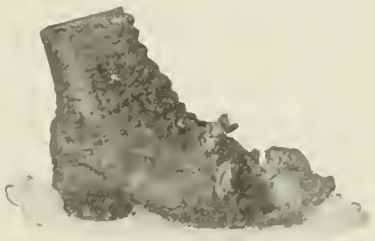
Resorcin in Rodent Ulcer.—There can be no doubt as to the value of resorcin in rodent ulcer. I have lately had a typical case, which was cured in five or six weeks by rubbing in the powder every night after removing the crusted covering, and ceasing the application when the reaction was excessive.—J. E. Blomfield.

Clinical Department.

LIGHTNING STROKE WITH RECOVERY.

By C. Edwards Sharp, M.D.,
Columbus, Ohio.

On May 18th—the eighteenth anniversary of the patient's birth—during a spring shower, Miss L. W—— went to the attic on the third floor of her home to close the windows. A flash of lightning struck her, and she was found with her clothing ablaze and lying unconscious on the floor of the apartment. Strange to state, the building did not catch fire, but a two-by-six rafter in the gable roof was badly splintered and a hole was made through the floor of the attic as if a gun loaded with buckshot had been used. Another member of the family on the second floor of the building was momentarily stunned by the stroke. I was called and reached the patient about ten minutes after the flash, to find Dr. A. O. Bonnet in attendance, but



we had very slight hope of recovery, and he soon left the case. The patient was found, as previously stated, in an unconscious condition; the pupils were widely dilated, there was stertorous and irregular breathing, but the pulse was apparently unaffected or slightly accelerated. The face was burned and the hair singed. The flesh on the chest between the nipples, that covering the anterior surface of the abdomen and mons veneris, the anterior surface of the thighs, and the right foot were burned. For a space just above the knee to the top of the shoe on the right side no marks of injury were visible. The shoe on the right foot was burst open as shown in the accompanying photograph. The crossings of the shoe-lacing were burned on the flesh, probably because the lacing was damp. The lacing itself was entirely missing. Otherwise the foot escaped injury and the left foot and leg were uninjured.

After this hasty examination the patient began to jerk spasmodically—first the right arm and left leg. Morphine and bromide of potassium were administered. The patient was then removed to a bed on the second floor. The spasmodic contractions increased and more morphine was injected. I summoned Dr. I. C. Edwards to the case, and he soon arrived; Dr. H. W. Whittaker also assisted for a few minutes. The pulse remained excellent, and a little chloroform soon quieted the tendency to spasm. The pupils now contracted to pin-head size, possibly due to the morphine.

The burns were dressed with carron oil, after the charred clothing had been carefully removed.

The patient continued in a comatose condition till about 6 A.M. the following morning, when she feebly called for her father. Upon being informed of the nature of her injuries, she said that she remembered nothing about the cause of her condition. She gradually rallied from the shock.

The burns were dressed antiseptically. The temperature at one time was 102.5° F. in the afternoon, but on closer attention to the dressings was controlled. The patient urinated more than usual, probably due to the impaired function of the skin of the burned surfaces.

The bowels were constipated, and cathartics and enemata were given. But on the afternoon of May 23d a moderate diarrhœa set in with bloody or tar-like passages. The temperature at this time was 99 F., and pulse rate 104. This bowel trouble yielded happily to treatment, and the patient at the present time is well both mentally and physically, except for the burns which are healing rapidly.

570 East Livingston Avenue.

SARCOMATOSIS OF THE VERTEBRÆ SIMULATING TUBERCULOUS OSTEITIS IN A CASE OF PULMONARY TUBERCULOSIS.

By T. HALSTED MYERS, M.D.,

NEW YORK.

ATTENDING ORTHOPEDIC SURGEON, ST. LUKE'S HOSPITAL.

PATHOLOGICAL REPORT BY

F. C. WOOD, M.D.,

PATHOLOGIST TO ST. LUKE'S HOSPITAL.

On December 25, 1899, I was asked by Dr. Le Fevre to examine the spine of a man in the phthisical ward at St. Luke's Hospital. I report the case as a contribution to differential diagnosis. He was forty years old, and as he lay in bed was unable to sit up or even turn without severe pain in the interscapular region. There was neither kyphosis nor curvature, but marked muscular rigidity in the upper dorsal and cervical regions. There was also tenderness over the fourth dorsal vertebra, together with some pain in the left mammary region and lower end of the sternum. The ribs were almost motionless and the respiration was abdominal. There were signs of old pleurisy on both sides and of consolidation of the lower lobes of the right lung. Tubercle bacilli had been found in the sputum on every examination. The man was emaciated, losing weight and strength rapidly, and had a hectic temperature. There were no symptoms of pressure on the spinal cord. Malignant disease was at once suspected, on account of the marked local pain and tenderness; but as malignant disease of the vertebræ is nearly always secondary, as we could discover no primary focus, as there was a good family history, and as active tuberculous disease did exist in the lungs, the diagnosis was reserved, as it seemed possible that an abscess about to point posteriorly might explain the local symptoms. A week later, examination showed a slight projection of the fourth dorsal spine and more pain along the intercostal nerves, but there was the same persistence of local tenderness and muscular rigidity. As every motion was exquisitely painful, a spinal brace was ordered. The patient now failed rapidly and the support was never applied, but it was not until February 23d, two days before death, that the diagnosis was made certain by the discovery of a nodule on the anterior surface of the liver.

In a paper on "Non-Tuberculous Inflammations of the Spine,"[1] I found that carcinoma and sarcoma are present in about equal frequency; that both may be primary, but are usually metastatic. Kyphosis is usually not present. The disease may occur at any age, but the average is forty-five years. The average length of life after the onset of vertebral symptoms, Amidon found to be eight months. Pain has been a prominent symptom in all these cases, motor paralysis less constant. The cachexia at times did not appear till late. The spinal nerves are often involved in the new growth. As Hodenpyl has said,[2] speaking of the association of malignant disease with tuberculosis: "The lesions are not antagonistic, though they usually occur at different periods of life. Carcinoma may be grafted on an old tuberculosis, and a tuberculous lesion may act as a predisposing cause in locating this deposit just as a traumatism might." This probably would apply to sarcomata as well. This patient had pleurisy four years ago. Acute pulmonary symptoms began four months ago.

From a point of view of pure pathology, the case is interesting because of the unusual distribution of the sarcomatous nodules and the impossibility of a certain determination of the situation of the primary growth. The kyphosis mentioned above was quite marked post mortem, the most prominent vertebral spine being the fourth. Just at this level and 3 cm. to the left of the spine was a tumor mass lying in the muscles and roughly oval, measuring 3 x 2 x 7 cm. This mass was quite soft and made the kyphosis more prominent by its bulk. The middle and lower lobes of the right lung were converted into a cavity half filled with purulent sputum. The bronchial lymph nodes were enormously enlarged, partly tuberculous and partly invaded by the new growth. The lymph nodes in the mediastinum were enlarged by tumor invasion, and many small, bean-shaped sarcomatous masses were scattered over the inner surface of the pleural cavity, lying just under the costal pleura and easily movable. The liver was 10 cm. below the costal arch in the mammary line. On its anterior surface was a tumor mass of moderate hardness, 8 cm. in diameter, and considerably raised above the surface of the viscus. Throughout the whole organ were numerous smaller nodules of sarcoma. The stomach showed no metastases, though its mucous membrane was covered with small polypoid growths a few millimetres long, and at one place was a small fragment of a pancreas about the size of a pea just under the mucosa, both of which conditions, though interesting, will not be further described, as they were not pertinent to the main lesion.

The spleen contained two moderately large metastases. The left suprarenal body contained numerous small nodules which resembled very closely miliary tubercles, as did also small scattered metastases in both kidneys. The left kidney also had two nodules, measuring about 1 cm. in diameter, lying just under the capsule. In the head of the pancreas was a large tumor, about 5 cm. in diameter, paler than the surrounding pancreatic tissue and shading off gradually into normal gland. There was no capsule or evidence of delimitation of the growth from the gland tissue. Two other nodules lay midway between the head and tail of the pancreas, each measuring about 1.5 cm. in diameter, and sharply marked off from the surrounding gland tissue by the color and texture. The pancreatic duct was patent. The retroperitoneal and portal lymph nodes were greatly enlarged and sarcomatous. The body of the fourth dorsal vertebra was softened and dislocated backward several centimetres, the new growth having invaded and softened it and, to a less extent, the bodies of the third and fifth vertebræ. The spinal cord was compressed slightly, but no changes could be made out microscopically. The spinal nerves at their exit from the canal were surrounded by the new growth.

The microscopical examination of all these growths showed them to be spindle-celled sarcomata.

Primary and, to a less degree, secondary sarcoma in the pancreas is of great rarity. Not over eight primary cases are on record. The rarity of secondary growths is said to depend on two seemingly rather insufficient causes: that the pancreatic arterial supply is derived from small lateral branches, chiefly from the splenic, and the metastatic particles are carried by in the main current; and secondly, that metastases may occur, but do not find suitable soil for development. The same peculiarity has also been observed in miliary tuberculosis; the spleen is very commonly, the

[1] Medical News, May 27, 1899.

[2] Transactions of New York Pathological Society, 1896, p. 20.

pancreas very rarely, invaded, though both are fed from the same vessel. The question of soil is important here also, for the rarity of tuberculosis in similar glandular organs, the parotid and submaxillary, is well known.

Spindle-celled sarcomata arising from the periosteum are not rare, and the probable course in this case was a growth from the periosteum of the fourth vertebra with subsequent invasion of the bone marrow, and thence a flooding of the general circulation with metastatic particles, and a secondary invasion of the pancreas, liver, and other organs.

EMBOLUS AND HEMIANOPSIA.[1]

By GEORGE DACRE BLEYTHING, M.D.,
NEW YORK.

Mrs. C. M. B——, aged fifty-seven years, married. On May 24, 1898, I was called to this patient, who made a statement of finding herself two evenings before, in playing a game of backgammon, unable to put her hand directly on her pieces or dice, her sight failing to guide her as to the location of the object sought. This became so annoying that she left the game and walked about, opened an outside door and stood in the air, and then returning and finding that she was not relieved, she gave up the game and went to bed. She had previously at times been troubled with floating objects in the field of vision, which disappeared after a dose of calomel, and she felt no special concern at these symptoms.

The following day she took her purgative, but on the second day sent for me and narrated this experience, with the additional statement that she could not read, as the page was interrupted by black bars.

Her general condition was found to be fair; the pulse, however, was intermittent, and upon examination the heart was found to have extensive valvular disorganization. There was an aortic direct murmur.

The patient had suffered from dyspnœa upon exertion for some time—a year or more—and now complained of headache localized about the right eye and through the head to the occiput. Ophthalmic examination showed no degeneration of the retina, but the test of the visual field discovered a distinct hemianopsia of the right eye, on the temporal side.

The patient was put to bed with orders for quiet, light food, and a shaded room—the last for relief from the impression of the marked limitations of the visual field.

With slight fluctuations as to digestion, gastric and intestinal, and of sleeping, the patient improved during May and June, the disorder of vision becoming less. The improvement was not alone from the patient's becoming accustomed to and ignoring the limitations, but the use of the perimetric test showed an actually diminished area of insensitive retina. The right eye showed slight outward deflection.

On July 2d Dr. H. H. Seabrook saw the patient and made the following report: "There is at present rapid exhaustion of the macular portion of the retina when the eyes are used, with rather indefinite complaints of metamorphopsia which must be due to cerebral causes, as examination of the refraction and ocular muscles shows: V O.D. = .6 with cylinder + .50 axis 90° = .8 at 20 feet. Orthophoria—abduction 6 . Jaeger No. 1 from 8 to 12 inches with spherical +3.50. Field normal, with the exception of 10° at periphery of temporal boundary of field of right eye."

Dr. M. Allen Starr saw the patient in consultation on May 27th. His diagnosis was central embolism (1) of the post-cerebral artery, involving occipital lobe; (2) of the middle cerebral artery, involving the internal capsule[1] and the motor speech area.

The prognosis was recurring emboli with an ultimately fatal result.

As, however, the hemiopia almost disappeared, and there was for a time no repetition of the former symptoms, I hoped for long relief from the detachment of growths and recurrent arterial occlusion; and on June 25th I left town for the summer, coming once a week only to see my patients.

When I returned on August 9th I found the patient under the ministration of Dr. J. Lee Morrell. Two days before she had attempted a bath, had fallen in the tub, and was unable to say whether a vertigo had caused the fall, or whether she had slipped and the shock of the fall had induced cerebral symptoms. The fall had been heavy and her ribs were injured by contact with the tub. Except for pain in respiration, no trouble followed this accident.

So through August and September such improvement in the general condition took place that the patient became restive, and finally so depressed from confinement in the apartment that she was permitted to go down-stairs every evening when she felt disposed to dine with the family.

On October 20th she was taken to her daughter's house in the suburbs for a change, and experienced little fatigue from the effort; on the contrary, she had increased appetite and better spirits.

The hemianopsia now ceased to be troublesome; the patient read and played cards and backgammon with ease.

On November 29th she came home, showing distinct loss of power in her right arm and hand. It was described as coming so gradually that she had not noticed a change from day to day, but felt now that it had begun about two weeks before. This paralysis showed that the blood supply of the motor areas was cut off by a new embolus, or that softening had supervened upon the first embolus and slowly extended.

On December 2d I was summoned early in the day to the patient, who had difficulty in calling words and was herself greatly alarmed at the symptoms. All signs of cerebral impairment now increased, the right leg becoming involved and the power of speech being gradually entirely lost.

During this time the patient was in an increasing degree emotional, and upon the first appearance of the various failures of functions showed mental distress, but at no time lost consciousness, with the possible exception of the time of the fall in the bath. The hemianopsia and the aphasia only were sudden in their onset.

On December 21st Dr. Starr again saw the patient, and his prognosis giving no hope, a daughter-in-law urged the services of her physician, who was a homœopath, and I withdrew from the case.

I was so interested in the patient as a friend and anxious for the best treatment for her, that I met the doctor and explained the case, the theory we had gone upon, and the treatment, giving symptoms as they had occurred, but leaving the new attendant to make his diagnosis. He saw her, felt her pulse, looked at her tongue, and without further examination of heart, urine, vision, or sensation, left the room with me and pronounced the case "sclerosis." He informed me the

[1] Read before Lennox Medical Society.

[1] The internal capsule consists of white fibres passing between the caudate nucleus of the thalamus opticus and the lenticular nucleus. The anterior portion consists of fibres from the anterior lobe, and the posterior portion of motor fibres from the operculum on their way to the anterior pyramid of the medulla oblongata. The lenticular nucleus of the corpus striatum is the largest portion and is lodged within the white substance of the hemisphere, being separated from the caudate nucleus by a layer of white matter—the internal capsule. The caudate portion is in the lateral ventricle.

case was hopeless, and he had taken it only at the solicitation of his patient.

His prognosis was verified four days later. There was no autopsy.

Undoubtedly the first lesion in this case was in the cortex of the calcarine fissure, now proved to be the site of the primary visual centres, and showing, as Dr. Starr had declared, that some branch of the posterior cerebral artery passing into the base of the occipital lobe was the seat of the embolus. The median cerebral artery (or a branch) supplying the inferior frontal convolution (Broca's convolution), now localized as the speech centre, must also have been in turn occluded, as softening would not extend from the posterior to the anterior lobe of the brain. The centre for movements of lips and tongue is placed in that relation to the fissure of Sylvius.

The portion of hemisphere overlapping the central lobe is called the operculum or lid. The fissure of Sylvius forms the boundary of this opercular lobe, which includes the central fissure of Rolando, and is demonstrated to be the controlling centre of the movements of the limbs and is likewise nourished by the middle cerebral artery.

This case is one of few reported, and is interesting in its comparative novelty and also important in its suggestion, in the early history, of apoplexy without paralysis of limbs or impairment of locomotion. Dr. M. A. Starr has reported[1] several such cases of apoplexy—one similar to the one here narrated. As Dr. Starr demonstrates, slight cerebral hemorrhages are often overlooked.

I have a case now under observation, belonging to that class in which numbness of the arm has been attributed to position in sitting or in sleeping, but which has been undoubtedly the result of slight cerebral hemorrhage.

I will quote Dr. Starr's case of hemianopsia: "Male, aged sixty-two years, who has a well-marked mitral regurgitant murmur and extremely rigid arteries, suffered in 1893 from a slight attack of left hemiplegia which passed away gradually, leaving a disagreeable and permanent sensation of numbness in the left hand. During the summer of 1896 he had an attack in which he noticed a headache, a sensation of vertigo, and a sudden obscuration of vision in the left eye. This was attended by a condition of prostration, in which he was seen by Dr. W. C. Campbell, who found his heart very weak and intermittent, but his mind perfectly clear. There were no anxiety, no aphasia, no paralysis, but an examination showed that the supposed dimness of vision in the left eye was really a bilateral left hemianopsia. In the course of two weeks the general symptoms subsided under appropriate treatment, and since that time he has been attending to business. The left homonymous hemianopsia remains, a careful perimetric diagram of the visual fields taken in October, and again in December, 1896, showing the blindness in the left half of both eyes."

27 East Eighty-first Street.

TWO CASES OF SELF-CASTRATION.

By J. E. COURTNEY, M.D.,

Poughkeepsie, N. Y.

Two remarkable, if not unique, cases of this rare form of self-mutilation have come under my observation. I think they deserve recording on account of both their psychological and their surgical interest. There is something at once grimly dramatic and repulsive in an act of this sort, and the literature of such patients, especially in modern times, is small. The motive, the premeditation, the psychological condition, the rough technique, and the ready recovery of the patients are notable. One patient was a religious fanatic and conceived the act from his reading; the other could not have read of any precedent. I have read of but one case nearly similar to these two; that is recorded in Tuke's "Dictionary of Psychological Medicine."

Neither patient was imbecile nor had any anæsthesia.

Case I.—John C——, aged twenty-six years, under commitment for burglary, was transferred to a State hospital for the insane. He was quiet and worked about the grounds. He removed one testicle under the following circumstances: He sharpened an old knife used for peeling potatoes, and made a little reticule bag in which to put the testicle, secured a sewing-needle and ordinary spool of thread, and, excusing himself a moment from his attendant, cut out the testicle and sewed up the scrotum. He asked the attendant to take him to the doctor, but gave no reasons. When seen, he was somewhat pale and laboring under suppressed excitement, and taking the writer aside he announced what he had done, saying that his "nerve failed him" as to taking out the other. There was little time for incredulity. With the utmost sangfroid he produced from his vest-pocket the little pouch containing the testicle. The scrotum was greatly distended with blood. The crude sutures were removed and the wound was dressed. The man quickly recovered. He explained that his purpose was to cure himself of masturbating, to which habit he attributed his crime and all of his troubles; he claimed later that he was "almost cured."

Case II.—O. P. F——, aged forty-six years, shortly before coming under my care removed one testicle, and had no medical attention until the second day after the act. I am indebted to Dr. Bird, of Hyde Park, N. Y., for the following account: "I was called to see O. P. F—— two days after he operated on himself, removing one testicle. There had been oozing of blood, and it was on this account that I was called. I introduced one suture. He said his object was to destroy venereal passion, and that if the loss of one testicle did not suffice he would remove the other. He said it did not hurt much. He recovered promptly."

This case was one of paranoia with hallucinations and delusions pertaining mostly to religious subjects. The line of argument leading to the act was that the original sin was sexual; that there were eunuchs who had made themselves eunuchs; "if the eye offend, pluck it out"; that "the old dispensation was founded on two tablets, two stones, the new on Peter, a rock, one stone," etc. He was quite clever in defending the act from the predication of insanity, and published a pamphlet in which he elaborated his arguments.

Intestinal Paralysis in Typhoid Fever.—E. P. Benoit reports a case which convinced him that the specific lesions of typhoid fever, while locally very dangerous and often determining fatal complications, may frequently cause but a slight ulceration of the intestinal wall and yet induce grave alterations in the coats of the organ by creating an entrance for the toxins of Eberth's bacillus. The danger to the intestine in such cases comes, not from the local ulceration, but from general infection, and the patient who has escaped death from hemorrhage, perforation, and peritonitis may succumb to intestinal paralysis. The author thinks that there is no way to avert the fatal issue. Electricity and other measures may be of use when the paralysis is due to defective nerve force, or to great intra-intestinal pressure, but the function of the organ can scarcely be restored if the muscular tissue is degenerated. One might as well attempt to overcome fatty degeneration of the heart by digitalis. —*L'Union Médicale du Canada*, July, 1900.

New Instruments.

A NEW NASAL-DUCT IRRIGATOR.

By HUGH E. JONES, M.R.C.S.,

SURGEON TO THE LIVERPOOL EYE AND EAR INFIRMARY, LIVERPOOL, ENGLAND.

The accompanying woodcut represents a cannula for irrigating the lacrymal sac and nasal duct. It has been used in its present form for two years and has given perfect satisfaction. The chief points about the instrument are the following:

1. It is made of silver.

2. The cannula is closed at the distal end and two

catheter eyes are cut as near the end as possible. In this way the use of the stylet is avoided, while it is practically impossible to injure the delicate mucous membrane of the duct while passing the cannula.

3. The outside diameter does not exceed that of Bowman's original No. 6 probe, so that it is necessary to divide only half the length of the canaliculus in order to pass the instrument.

4. There is a tap at the proximal end of the instrument whereby the flow from the irrigator (which should be at least six feet above the patient's head) may be controlled by the hand which handles the instrument. If preferred the cannula can be obtained without the tap, and a clamp used on the irrigator tube.

A NEW CURETTE.

By E. W. PEERY, M.D.,

RURAL RETREAT, VA.

The instruments now in use for curetting the uterus are inconvenient and unsatisfactory. They are inconvenient because the patient has to be placed before a light, a speculum must be adjusted, and often it is necessary to call assistance. The methods are unsatisfactory because, in using them, the hand is some distance from the uterine cavity and the sense of touch is necessarily in great measure lost; after the operation one is not sure that all retained portions have been removed; and in cases of uterine flexure it is almost impossible to reach and curette the whole endometrium. One is really groping about for the retained portions of placenta, and the scraping process is usually prolonged by the operator so that he may feel more certain of the complete removal of adherent portions. This is likely to cause injury, especially when the sharp curette is used. For these reasons most physicians remove retained portions with the finger when it can be done, and it is only in cases in which this is not possible that the long-handled curettes and forceps are used.

The curette here shown is more efficient than the finger, and it has not the disadvantages of the long-handled curettes. This instrument is to be worn on the finger, and may be used in those cases in which the cervical canal is already open, or after its dilatation. While the instrument is especially useful in cases of incomplete and induced abortion, it may also be used in cases of fungous and decidual endometritis, in cases of multiple polypi of small size, and of polypi arising from placental tissue; in obstetrical cases to remove portions of placenta, and in the puerperal state to curette the uterine cavity when there are symptoms demanding such a procedure.

The advantages claimed for this little instrument are these: 1. As the blade is broad and round, and the cutting edge semi-sharp, as the sense of touch is better, and as the finger is within the uterine cavity gauging its depth, there is not so much danger of injuring the parts.

2. Being placed on the finger, it enables the operator to reach easily the fundus uteri, and the retained portions or other abnormal tissues hanging from this or other parts of the uterine walls are easily scraped away.

3. By its use the finger is lengthened so that the fundus can be reached in most cases by introducing two fingers, and in every case can be easily reached by inserting the four fingers up to or a little above the metacarpo-phalangeal joints, so that the whole hand need not be introduced; consequently there is not so much stretching of the vaginal walls, and therefore less pain.

4. It enables the physician to do the work in half the time required without it, thus lessening the danger of prolonged hemorrhage and the suffering of the patient.

5. By its use portions of decidua which may adhere high up in one or the other cornu can be removed more easily than by any other means at our command.

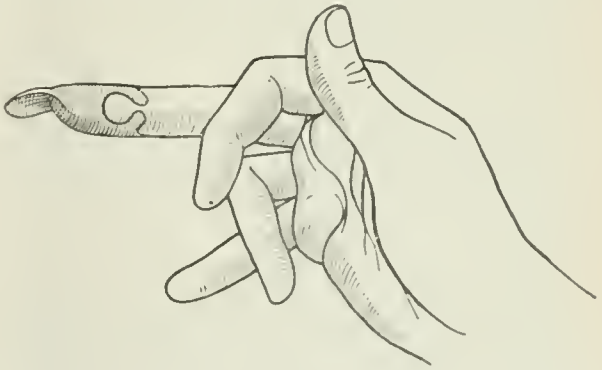
6. The finger-nail which must enter the cavity of the womb is practically sealed, doing away with another possible source of infection.

7. It not only separates the adherent decidua or placenta easily, quickly, and safely, but the cup-like portion makes it easy to withdraw pieces from the uterine cavity, which is often difficult with the finger alone, especially in cases of unyielding or of hour-glass contraction.

8. Its employment does not necessitate the use of speculum and light, and as a consequence a certain amount of exposure which every woman dislikes.

We see, then, that this little instrument, applied to the finger, supplies a long-felt want, and is a most efficient means of curetting in nearly all cases. We also see that it has great advantages over the old curette, even in cases in which the latter can be most efficiently used. Then we meet some cases in which the older instruments are almost entirely useless. In cases of abortion when the womb is flexed or impacted below the sacral promontory, it is almost impossible to reach adherent parts with them. With the finger-curette they can be easily reached and separated, regardless of the position of the womb.

Soon after parturition it is often necessary to curette the placental site, but as the uterus usually is



bent on itself, the long curettes cannot be used satisfactorily, and often are of no service at all; while with this instrument on the finger any curvature may be followed; consequently the work is done with ease and certainty.

One should first pass the finger into the uterine cavity and note its size; also the size and position of

fungosities or retained portions of placenta; then the instrument may be placed on either the fore or middle finger, but it is most easily introduced on the forefinger. With the curette on this finger and resting against the palmar surface of the middle finger, the two fingers should be passed into the vagina, and then, using the middle finger as a guide, the operator will find the cervix and pass the forefinger around with the curette into the uterine cavity. The other hand should be placed over the upper pelvic strait, pressing the womb down and supporting it while the curetting is being done. In using this curette one need not expect to feel the adherent portions as he would with the finger alone, but he should boldly sweep the instrument around with sufficient force to detect the firm uterine wall. This is not hard to recognize, and one need have no fear of doing damage when this curette, which is semi-sharp, is used.

Surgical Suggestions.

Burns not exceeding degree of vesication.—

℞ Tannin,
Alcohol.....āā 1 part
Sulphuric ether..... 8 parts
—Nikolsky.

To Prevent Sloughing.—Cover by means of a brush the parts threatened, with two coats daily of:

℞ Gutta-percha..... 4
Chloroform..... 30
Balsam of Peru..... 1

Iodine Ointment which does not irritate the skin:

℞ Amyli iodidi..... 3 gm.
Lanolin..... 30 "
Spir. canellæ..... gtt. iij.
M. S. For external use.
—Verbitzky, *Gaz. Hebd.*, August 12, 1900.

Hay Fever.—Cauterize repeatedly the hyperæsthetic areas.—Roe.

Myomectomy for submucous fibroid was done by Braithwaite in an almost bloodless manner. The drainage tube was removed in twenty-four hours. There was uninterrupted recovery.—*Scalpel.*

Shock.—Horizontal position, hot bottles to epigastrium and feet, warm affusion to the head, and warmth generally. Frictions, stimulants (brandy, ammonia), and galvanism to the precordia.—*Medical Summary.*

Fissured Nipple.—Bathe the nipple daily during the last month of pregnancy with tincture of quinine. Avoid all ointments.

Early Tapping is now advocated as giving relief to the patient and tending to prolong life in the ascites of cirrhosis. It is better than to employ purgatives and diuretics. Aseptic precautions do away with the dread of infective peritonitis.

For Disinfecting the Hands.—Tests with spiritus saponis (P. G.) have confirmed its efficacy in the disinfection of the hands. It renders them as free from germs as it is possible to have them with our present methods, while it has no injurious effect on the skin. —Hanel.

Umbilical Infection in the new-born is a not infrequent cause of death. The wound may have appeared healed several days before death occurs. It is never possible to affirm that an umbilicus is entirely healed until from fifteen days to three weeks after birth. Among the affections are primary putrefaction of the cord, fungous growth, tetanus, erysipelas, blennorrhagia, ulcer, abscess, phlegmon, phlebitis, and arteritis.—Audion.

A Chloroform Mask is preferable to a piece of lint or towel end, because of the possibility of burning the nose and lips with the latter.—Gardner.

Medical Items.

Typhoid in South Africa.—A correspondent writing to the London *Lancet* from South Africa says: "By far the largest number of our patients are suffering from typhoid fever of a very severe type. The chief strain seems to fall upon the circulatory apparatus, and weak running pulses of from 130 to 144 are not uncommon. The reason for this seems to be that the patients before contracting the disease have had excessively hard work to do, riding and marching for many hours every day, and this has no doubt weakened the resisting-power of the heart in a disease which is known to severely attack the muscular structures throughout the body. Liberal quantities of champagne and brandy with digitalis and strychnine have to be given to tide the patient over his difficulties."

Increase of Insanity in Great Britain.—There can be little doubt that insanity is on the increase not only in Great Britain but throughout the civilized world. Dr. W. W. Ireland, a British lunacy expert, has recently, says the *Medical Press*, addressed a series of questions to a number of leading men in the country in order to ascertain whether they have observed an increase in the relative frequency of diseases of the nervous system. Several doctors give their opinion that nervous diseases are on the increase, and their testimony is quoted as having an important bearing on the lunacy problem. Undoubtedly there is a great deal of common sense in this view, and there can be but very little question that nervous diseases come more under notice than formerly. Professor Erb gives, as among the factors producing nervous diseases, irritation and depression, the greater anxiety, hurry, mental toil of life, overwork at school, and so forth. It is probable that lunacy is really more on the increase than authorities will admit.

Ruskin's Dislike of Bicycling.—A few days before Ruskin's death a New York editor despatched his London representative to interview the sage of Brantwood on the beauties and benefits of bicycling. Ruskin, following his usual custom, gave the newspaper man so cold a reception that the latter lost no time in making his return trip to London. A few days later the correspondent received a letter from Ruskin in which he said: "Some time ago I put myself on record as an antagonist of the devil's own toy, the bicycle. I want to reiterate with all the emphasis of strong language that I condemn all manner of bi-, tri-, and 4-, 5-, 6-, or 7- cycles. Any contrivance or invention intended to supersede the use of human feet on God's own ground is damnable. Walking, running, leaping, dancing are the legitimate and natural joys of the body, and every attempt to stride on stilts, dangle on ropes, or wriggle on wheels is an affront to the Almighty. You can't improve on God's appointed way of walking by substituting an improved cart-wheel."—*Current Literature.*

The Antituberculous Movement in France.—In consequence of the publication in the *Revue Générale des Sciences* of some articles by Dr. Romme on sanatoria, he was asked not long ago, says the *British Medical Journal*, to deliver a lecture at Versailles on

the same subject to a number of foremen, tradesmen, and employees. So successful was he in impressing them with the practical importance of the question that they resolved to take immediate steps in the matter. They approached the municipal council, then on the eve of a new election, and the reply they got was that means would be sought for the creation of a district sanatorium for necessitous tuberculous patients. This reply being considered somewhat vague, three hundred and sixty electors, represenitng all shades of political opinion, demanded a more explicit pledge, taking the precaution to make the demand public by placarding it all over the town. In deference to this wish the council replied with a placard to the following effect: "Certain electors ask us to give formal promises on the question of a district sanatorium for tuberculous patients. Had it not been our intention to carry out the measure proposed we should have passed it over in silence. In promising to seek for means to realize it, we have, as is fitting, a firm intention of finding them; but a preliminary inquiry, for which we will without delay collect materials, is necessary." At the same time one of the political parties opposed to the outgoing council expressed its adhesion to the manifesto of the advocates of the sanatorium, and the leading members of another local party, certain of whom had signed the manifesto, individually pledged themselves in the same sense. This is said to be the first time in France that the feelings of a municipal electorate have found expression on the question of sanatoria. It is to be hoped that the example of Versailles will be followed in other parts of France.

Sins of Commission are charged against certain Chicago physicians by a Chicago editor. Dividing the specialist's or surgeon's fee with the family physician who refers the case is not looked upon as ethical or strictly honest by New York physicians in general.

The Proper Time to Begin the Treatment of Cross-Eyes.—Vard H. Hulen makes a plea for early attention in strabismus, pointing out the danger of altered vision and incurable defects resulting from neglect in the hope that time will cure the squint. It is a common and grave error to suppose that nothing can be done until the child is six or seven years of age. Many patients can be cured without resort to operation if seen early.—*Occidental Medical Times*, August, 1900.

Hospital Scandals in South Africa.—The following remarks in the *London Daily Graphic* express the opinion of the British public with regard to the charges brought against the methods of caring for the sick in the Transvaal campaign: "Amid the conflict of evidence from South Africa on the question of the hospital scandals, two points seem clear beyond dispute: first, that the individual members of the Army Medical Corps worked with untiring devotion; and secondly, that the corps as an organization was incapable of dealing adequately with the heavy work suddenly sprung upon it. The breakdown is variously attributed to War Office red tape, to the want of independent transport, and to the necessary difficulties of warfare in a huge and generally barren country. It is impossible, however, not to feel that beyond these causes there is also a deficiency in the composition of the corps itself. Every one is aware of the difficulty that the War Office has experienced in recent years in filling up vacancies in army medical service. In spite of concessions with regard to title and military rank, the best medical men have steadily refused to enter the army. The reasons are obvious: in the army a medical man finds neither good professional experience nor good pay. Why, then, should he sacrifice all the chances which civilian life offers? The mere pleasure of filling up War Office returns which nobody reads is not sufficient to attract the man who loves his work or the man who loves his leisure. If the army wishes to get better doctors, it must pay them better, give them larger opportunities of civilian practice and of returning to civilian life, and must worry them less with the tomfoolery of the red-tape system."

Mosquitos and Malaria.—Dr. Irving C. Rosse says: "During a considerable residence in Southern France and in Italy, I had frequent occasion to study this question. Monte Carlo is most prominently associated in my mind with broken sleep caused by mosquitos during an autumnal visit. Yet among those of my personal acquaintance with the same experience, none has since shown the slightest trace of malaria. A similar remark applies to Leghorn and to Rome, where, owing to the most important changes in public hygiene that Europe has ever witnessed, malarial fever is seldom seen except among the poorer classes. Englishmen and Americans, who constitute two-thirds of the foreigners in Rome, now reside there for years without an attack of malaria, in spite of mosquitos and of what the Italians consider their eccentric and independent habits. The old tradition of applying to almost every ailment, from a cold to enteric fever, the general term, 'Roman fever,' a vague disease that has no place on the nosological table, has created a prevailing notion hard to correct. As a matter of fact, the study of mortuary statistics and the sanitary condition of Rome, where I spent some time as sanitary inspector for the government, show that with the exception of London it is the best-watered, the best-drained, and the healthiest capital in Europe; and that a European or native of New England runs greater risks of contracting malarial fever in Washington, where it is more prevalent and where Anopheles are equally aggressive. The latest medical information from South Africa shows the entire absence of malaria in many localities where mosquitos are most troublesome. An old and experienced practitioner of New Orleans tells me that the same is true of Louisiana, notably among residents of the salt marshes, extending from six to fifteen miles inland from the Gulf. On the other hand, I am told that malarial fevers are common in the foothills of Virginia, as at Charlottesville, where mosquitos are such a negligible quality as to be almost unknown."

Lord Lister in Paris.—A pleasing and striking proof has recently been afforded in Paris that race animosity has no place in the realms of science. Notwithstanding the bitter, not to say rancorous, feeling displayed by a portion of the French people and press against everything English, the reception of the British men of science who took part in the International Medical Congress was hearty to a degree. Lord Lister, indeed, was the hero of the meeting, and the welcome he received at the hands of his French brethren could hardly have been excelled in warmth and spontaneity. Dr. Fleury, in *Le Figaro*, comments as follows upon the appearance and character of Lister: "Very tall, with a fine large head, white curling hair, gray whiskers, a smooth upper lip and chin, magnificently clear eyes which are at the same time dreamy and merry, like the eyes of a child; calm, courteous, and good-natured. Such is the impression which the inventor of the antiseptic treatment made on me when I happened to see him at the removal of the ashes of Pasteur. He came then at the head of an important delegation of English savants to pay homage to his real master, thanks to whom it had been possible for him to save hundreds of thousands of human lives and to increase tenfold the domain of reparative surgery. He is seventy-three years of age. If he seems now

somewhat aged and broken since the last few months, it is because he has lost, after a short illness, the admirable companion who was in every sense of the word the half of his life, the *dimidium animæ suæ*. Let us honor and fête Joseph Lister. The opportunity offered us will not be soon repeated. Innovators who bring to a branch of our activity such complete and magnificent reforms are rare. The work of this scientific son of Pasteur is of incalculable scope. Scientific surgery dates from him."

Alleged Poisonous Bullets.—On examining some of the alleged poisonous bullets brought to England by Sir W. MacCormac which the Boers were reported to have used, it was found that the charge was totally untrue. The green coating complained of was not verdigris but a comparatively harmless product of the reaction of the metallic casing of the cartridge upon a wax coating used to prevent damp and wet.—*Tit-Bits*.

Corporal Punishment in Schools.—The question of corporal punishment in schools has been much discussed lately in Germany and Switzerland, and the Canton Berne has come to a decision in the matter. *The Ethical World* considers the new law a compromise between the flagellants and anti-flagellants. It prescribes the use of the cane for "grave faults" such as indicate moral perversion; repeated lying is given as an instance, and it is expressly forbidden to punish for want of application. Girls are not to be punished physically at all.

Delusions.—The fact that emotions often form the starting-point of primary delusions furnishes an important indication as to treatment. As long as we are unable to exert any direct influence on the functional disorder itself, *i.e.*, on the nervous retro-action, our efforts must be directed toward the possible source, the emotion. Every one who is obliged to deal with paranoiacs knows by experience that the best way to get along with these unfortunate patients consists in a careful avoidance of all exciting agents, whether they come from within or without, and that these patients will do best if their minds are absorbed by some mechanical occupation which will guard the moods from injurious fluctuation. The beneficial result of this purely empirical treatment furnishes, therefore, a further support to the theory of nervous retro-action.—"Psychical Mechanism of Delusion," by Dr. Hirsch.

Death from Apoplexy, Not Nitrous Oxide.—At the discussion on anæsthetics before the New York County Medical Association, a report of which appeared in the Medical Record, vol. 57, page 438, Dr. Hobart A. Hare, of Philadelphia, alluded to a case in his city in which death had resulted from the inhalation of nitrous-oxide gas. It appears that this case occurred in the practice of Dr. John D. Thomas, who took occasion, at a recent meeting of the New York Odontological Society, to explain how the case had been misreported in medical literature. This death should not have been attributed to nitrous oxide, according to Dr. Thomas, who writes:

"This was not a case of death under nitrous oxide at all. The gentleman was a personal friend of mine, and had taken the gas upon three previous occasions, and there was no apparent indication that he should not take it again. The gas was given, and the right upper second and third molars were extracted. His recovery was complete in the usual time, and he rinsed his mouth with a tumbler of water while sitting in the chair. I had gone to my desk in another part of the room; and he arose from the chair and walked to the washstand, ten feet away, filled the glass and returned to the cuspidor beside the chair, and continued rinsing the mouth while standing, conversing with me in the mean time. This he repeated until he had used three glasses of water, occupying at least twenty-five minutes, after which he stood before the mirror and with his right hand drew back his lips and endeavored to see where the teeth had been taken from. As he removed his hand he looked at it and said: 'That hand feels numb.' He looked a little pale, and as my first thought was that looking at the wounds had made him feel faint, I directed him to lie down upon the couch while I proceeded to get him some brandy; and then I realized that his speech was thick and indistinct. Physicians were immediately summoned and everything was done to save him, but he died about four hours afterward. The coroner's jury gave the verdict of death from apoplexy, and stated that the gas was not the cause of it, in accordance with the medical testimony given there. The gentleman was certainly in such a physical condition that any exciting cause might have produced the same effect, and his taking the gas was but an incident leading to that effect. When we think of the many cases of sudden death with people in apparently good health which occurs on the street, on the cars, or in their homes, and take into consideration the nervous condition in which the many thousands who are to take the gas approach the dentist, it is really wonderful that there have not been numerous deaths either before or after the operation. I once made an appointment to go to a gentleman's house one morning at nine o'clock to administer the gas, and he died during the night preceding. Another man came to my office while suffering from grippe, and I refused to give the anæsthetic, but advised his return home, and promised to go to his house in a few days, when his physician was to be present. He died the next day. I have notes of another almost precisely similar case."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 31, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Alaska, Cape Nome	From beginning of outbreak to August 23d	23	
Colorado, Denver	August 11th to 15th	3	
Garfield Co.	August 4th	1	
Las Animas Co.	August 7th	1	
Louisiana, New Orleans	August 18th to 25th	9	2
New York, New York	August 18th to 25th	..	1
Ohio, Cleveland	August 18th to 25th	4	
Dayton	August 18th to 25th	1	
Portsmouth	August 18th to 25th	2

POISONOUS SNAKES AND SNAKE POISON.[1]

BY GUSTAV LANGMANN, M.D.,

NEW YORK,

FROM THE DEPARTMENT OF PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

THE zoological order Ophidia is popularly divided into non-poisonous, or harmless, and poisonous snakes. Such division appears quite natural, yet it is neither practical nor is it based on anatomy or biology; for in practice it is impossible to distinguish an innocent snake from a similar poisonous one by easily recognized characteristics. The law of mimicry is quite extensively displayed in reptiles, so that even experts after a hasty examination have been subject to fatal mistakes. Harmless and some poisonous snakes have certain anatomical features in common.[2]

You may remember from the study of comparative anatomy that snakes are provided with two rows of palatal teeth besides the usual marginal teeth of the upper and lower jaws; both run almost parallel. The teeth, solid pointed hooks, are curved backward; they are used for hooking the prey rather than for purposes of attack or defence. When the very dilatable mouth is repeatedly opened, the teeth are at the same time thrown forward so that the prey is gradually dragged down into the widely distensible œsophagus. In the innocent snakes the teeth in both jaws extend back almost to the commissure of the mouth; in the poisonous snakes, however, the strength of the whole row of marginal teeth of the upper jaw is, as it were, concentrated into one powerful tooth, the poison fang, which projects at the distal end of the maxilla. It is true, you will often find two or three teeth at this point; these are succedaneous teeth, which fix themselves into place when the snake has broken the main fang or lost it while shedding its skin. Such a fang is, as a rule, replaced by a new one about every six weeks; the old one is loosened by odontoclasts in Howship's lacunæ, just as are the milk teeth of an infant.[3] The fangs are firmly inserted, standing immovable in one family of the venomous snakes, the Colubridæ venenosæ, to which the cobras and hydrophids belong; in the other, the Viperidæ, including the true vipers and pit-vipers, they are erected for biting and are folded like a pocket-knife when at rest. This mechanism works in this way: the pterygoid muscles act on the shortened and vertically situated maxilla in which the fang is firmly fixed.

Another division is sometimes made by classifying the snakes according as they have short, cone-shaped, furrowed fangs, or are provided with long, pointed, tubular ones. This condition is brought about developmentally in the first instance by the folding of the dentine, which leaves a longitudinal furrow along the anterior surface; and in the second by a complete approximation, which produces a perfect tube. To the first class, the Proteroglypha, belong the Hydrophids and Elapidæ, or cobras; the latter class, the Solenoglypha, comprises the vipers and pit-vipers. The intensity of a poisonous bite is not dependent upon the shape of the fangs, except that a longer tooth, such as that of the viperine snakes, is capable of injecting the poison to a greater depth; indeed, the viperine poison apparatus is the most perfect of any in the venomous snakes.

We have to consider a third class of poisonous serpents, the so-called Opisthoglypha, the furrowed fangs of which, as the name indicates, are situated toward the rear of the mouth. There has long been a doubt as to whether they should be classed among the poisoners; and for this reason they were grouped together under the name of "suspecti." Recent investigations, however, have proven to a certainty that they also poison their prey, which mostly consists of small, cold-blooded animals. Catching them first with the innocuous front teeth, they push them gradually backward into the reach of the poison in the back teeth, to the action of which they soon succumb.

The poison apparatus is completed by the addition of the poison gland, which is closely in contact with either side of the skull, directly behind the eye, and is under the influence of the overlying masseter muscle. In some small East India snakes, Callophis, the elongated glands extend into the abdomen, so that they are emptied by a vigorous contraction of the muscles of the whole body. The efferent duct of the gland does not lead directly into the hollow of the fang; if it were so, every shedding of a fang would necessitate the formation of a new duct; the glandular secretion flows into a groove of the mucous membrane, which adapts itself directly to the base of the fang.

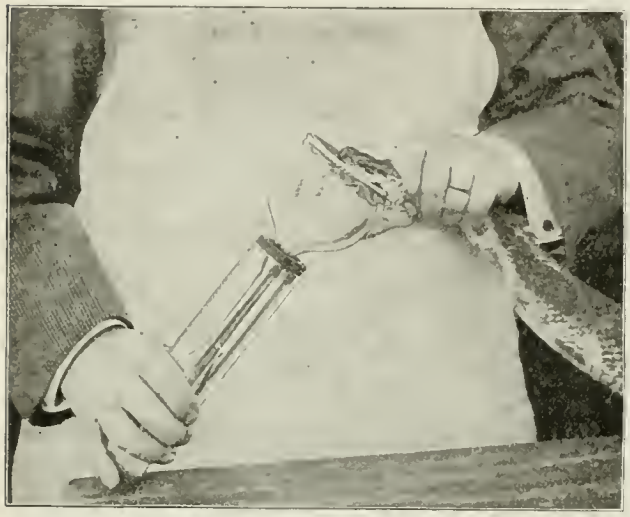
Poisonous snakes are found in all countries of the temperate and more so of the tropical zone. Numerous genera of the Hydrophids, elegant swimmers, with a laterally compressed tail, swarm through the whole intertropical part of the Pacific Ocean; their bite is justly dreaded. The tropical islands, however, and tropical countries of the old continent, are haunted by the worst kind of snakes, the Elapidæ. A large number of genera and innumerable types of every genus render parts of those countries, and especially of the islands, almost uninhabitable. The chief representatives of this genus are the cobra di capello (Naja tripudians) and the somewhat smaller though not less dangerous krait (Bungarus fasciatus), both living throughout the whole of East India. The most formidable is the king-cobra or hamadryas (Ophiophagus elaps), the largest of all poisonous snakes; it attains a length of fourteen feet, and it alone enjoys the reputation of attacking and even pursuing man. Its nearest relative, the aspis of Cleopatra (Naja naje), the symbol of the Egyptian kings, lives throughout almost the whole of Africa. In the western world this genus is represented by the beautiful coral snakes alone: one of them, Elaps fulvius, lives in our

[1] Read before the Academy of Medicine, New York, May 17, 1900. It is impossible to condense the extensive material regarding this topic into the paper of one evening. The paper must necessarily show many gaps and deficiencies, and as such is to be considered merely as an introduction to the study of snake poison.

[2] A fact which is indicated by the usual division of snakes into Colubridæ, comprising all harmless snakes, Colubridæ venenosæ and Viperidæ.

[3] Katharinер: Würzburg. Sitzungsber., 1896.

Southern States, where it is little feared, on account of its alleged good-nature, or rather its lack of irritability; its poison is, however, as active as that of its East Indian relative. Snakes are very numerous in Australia. Two-thirds of these are poisonous, and they belong exclusively to the family Elapidæ; the tiger snake, Hoplocephalus curtus, and the black snake, Pseudechis porphyriacus, have a fearful reputation. Europe has none but various species of vipers: the well-known common viper, Pelias berus, lives in Germany, England, and chiefly in France (Viaud Grand Marais counted in the departments of Vendée and Loire Inférieure alone in six years three hundred and twenty-one cases of bites with sixty-two deaths, in Auvergne fourteen with six deaths); in the south, around the Mediterranean the sand viper (Vipera ammodytes) is found. East India again has one of the most formidable vipers, the chain viper (Daboja Russelii); and Africa there is the very sluggish but very poisonous puff-adder (Clotho arietans). The greatest number of species of vipers are found in America, most of them belonging to the sub-family of the Crotalidæ



or pit-vipers, so called from a deep pit lying between the nostril and the eye.

The object of this pit, which sinks into a cavity of the maxilla—as it were, a reversed maxillary sinus—is entirely unknown. Leydig, of Bonn, calls it the seat of a sixth sense, which means nothing else but that he has no explanation. I have been able to investigate this pit to some extent. The bottom of the pit is covered by a thin membrane, the continuation of the external integument. Under this membrane, which shows abundant ramifications of nerves, there is a cavity which opens by a duct at the anterior margin of the orbit. According to the careful investigations of my friend, Dr. Pollitzer, who followed it up by serial sections, the nerve connects with the auditory nerve. Pricking or any other irritation did not produce any reaction, nor did the destruction of one or both membranes have any effect upon the movements or the hearing of the snake.

The chief representatives of the pit-vipers in the United States are the rattlesnakes. The banded rattlesnake (Crotalus horridus) is present throughout the whole territory from the Atlantic to the Rocky Mountains and far into Canada. Of the remaining six species of rattlesnakes we have to note the largest of all our snakes, the diamond-back (Crotalus adamanteus) of Florida and the South, and the swift prairie-rattler (Crotalus confluentus) in the Mississippi valley and the great Western basin; finally the smallest of all, the massasauga or ground-rattler. To the same sub-family belong the southern water-snakes, the moccasin (Ankistrodon piscivorus)—sluggish animals which are not a little dreaded by the negroes working in the rice-fields; and finally the beautiful copperhead (Ankistrodon contortrix), which is not at all rare in the whole East—in fact, lives almost in the same expanse as the banded rattlesnake. In the tropics almost all species grow to a larger size; thus the copperhead is repeated in the larger *fer de lance* (Bothrops lanceolatus) of the West Indies; the rattlesnakes of Central America grow larger, just as does the Crotalus durissus; and in the Orinoco valley there lives the bushmaster of the Dutch settlers (Lachesis mutus), next to the Hamadryas the largest of all poisonous snakes.

Let us now consider the poison apparatus. The poison glands, button-, tube-, or almond-shaped, with anterior elongated duct, are situated behind either eye, and when extraordinarily developed, as in the Crotalids, give to the head that triangular shape which was erroneously considered the characteristic of all poisonous snakes, and which gave to some species the name Trigonocephalus. The glands are the homologues of the common parotid; of the latter it is also well known that it alone produces an albuminous secretion. As to structure, they belong to the compound racemose glands with elongated acini; the glandular substance has columnar, the duct pavement epithelium. They respond to the action of belladonna exactly like any parotid gland.

A slight thickening of the duct is caused by a circular constrictor muscle, so that the snake is able to retain its secretion at will; and indeed it may be thus retained and not used for months. While the mouth opens, nothing flows out, and only when the masseters in closing the jaw compress the glands a fine stream squirts out of the pointed teeth. The secretion of the other salivary glands and of the mouth is alkaline, while the poison is always acid. The color of the latter varies from a straw or greenish-yellow to a deep orange. The viscous fluid, either clear or turbid (bitter in Naja), is not odorless as often asserted; it has a specific smell for every species, which is not easy to describe, but easy to recognize, thus the odor of crotalus poison may be called "mousy"; its specific gravity varies from 1.030 to 1.077; the solids are variously stated as from twelve to sixty-seven per cent.; my own samples are mostly dried down to twenty-five or twenty per cent. of the original weight. The dry poison cracks in scaly translucent chips of a light yellow or deep brown color, and also has a characteristic odor. Fresh poison under the microscope shows nothing but a few scaly epithelia and a number of finely granulated, amorphous, albuminoid masses, which undergo no change in a hanging drop, even after a long while.[1] It was often and even is to-day asserted that bacteria or cocci exist in the poison. To establish this positively, I sterilized my collecting apparatus thoroughly, and not the least sign of bacterial life was seen in broth or gelatin cultures of the fresh poison; also in acid media in which the experiments were repeated no trace of life was to be found. In order to determine whether the poison which itself destroys life might for that reason be free from mi-

[1] It may be of interest to describe my method of collecting poison. It ought to be said in advance that poisonous snakes, as a rule—at least those of our country—are of a timid and retiring, rather than of an aggressive disposition. They are taken out of their cage with a curved stick on which they remain hanging, afraid to fall. Then they are laid upon a table or upon the floor, and, while they are stretching out to crawl away, their head is tightly pinned down to the table with the stick. The index finger and thumb thereupon grasp the neck of the snake behind its head so firmly that it cannot be turned. A funnel over which a chamois skin or thin rubber is tightly drawn is held in front of the snake, which throws both of its fangs through the cover of the funnel; the poison drops out of the fangs into the funnel and into a glass beneath the latter. While the snake is holding on its glands may be compressed to squeeze out the last drop. The liquid poison is either mixed with equal parts of glycerin or it is dried under a bell-glass with sulphuric acid or calcium chloride.

crobes, I mixed fresh poison with bacillus subtilis and bacterium coli for one-half hour and then inoculated it on gelatin. The growth was lively, even more lively than in the control plates, probably because the gelatin was liquefied at the points of contact with the poison.[1] A bacterial action, therefore, cannot be assumed; the rapidity alone with which the poison acts in the system would exclude bacterial influence. What, then, is its active constituent? The first chemical analysis was made in 1843 by Prince Lucien Bonaparte, who established the albuminous nature of viper poison and called the poison "viperin." Almost twenty years later, 1861, Weir Mitchell found a similar proteid in crotalus poison, which he named "crotalin." Other investigators claimed to have found alkaloids or ptomains, when Weir Mitchell again, in conjunction with Reichert, published in 1883 the results of their studies, that the active principle of snake poison was an albuminoid, but instead of one they had discovered two. One of them, easily dialyzable and coagulable by heat, was called venom-peptone; the other, not dialyzable and not coagulable by heat, venom-globulin. The proportions of both were not alike in cobra and crotalus poison; even among the Crotalidæ they found wide differences. Thus cobra poison had ninety-eight per cent. of peptone and two per cent. of globulin, but moccasin venom had ninety-two per cent. of peptone and eight per cent. of globulin, diamond-back only seventy-five per cent. of peptone and twenty-five per cent. of globulin. Besides the proteid there are a coloring substance, several salts, and some fat. Mitchell's report was mainly corroborated in 1886 by Wolfenden in England, who discovered globulin and several albumins in variable proportion in the poison of cobra and daboja; one of the latter he designated serum-albumin; the other, corresponding to Mitchell's peptone, syntonin or albumose. Kanthack's analyses likewise demonstrated the presence of a proto- and hetero-albumose in cobra poison. Martin and McGarvey Smith found also a harmless albumin and two very toxic albumoses in the poison of the Australian snakes. It may be asserted that in no instance has a definitive analysis of any poison been worked out to this day, but all investigations centre in this one fact, that the active principle in all snake poisons is some form of albumose.[2]

In default of accurate analyses, I will use the convenient terms, venom peptone and globulin, in our further discussion. Not only do the various poisons differ in the percentage of peptone and globulin, but also in the toxicity of the constituents themselves.[3] The venoms retain their efficacy for long periods of time under suitable conditions; poison, when dried or mixed with glycerin, has proved itself as active as fresh poison, even after a lapse of twenty-two and twenty years respectively. Freezing continued through weeks does not alter it; putrefaction destroys it after a long time, but it is soon changed by heating when the temperature is raised to different heights, according to the different chemical composition. The easier coagulable globulins are rendered innocuous at 80° C., while the peptones are destroyed only by applying heat for hours. The coagulated proteids are inert in this condition, but they regain their toxicity when redissolved. It is the more or less evident capability of chemicals to coagulate proteids which determines their relative power of destroying the efficacy of venoms, when they are mixed with the poison in a test tube for experimental purposes. Alcohol renders it inert for a time only. Absolute alcohol seems to coagulate all poisonous ingredients, but the presence of an infinitesimal part of water is sufficient to retain the toxicity of the supernatant fluid. Poisonous serpents, when preserved in alcohol, have to be handled, even after years, with the greatest care, as has been demonstrated by a fatal accident to an assistant in the St. Petersburg Museum.

The physiological effects of both ingredients named, whenever they are tested separately in animals, are widely different. The peptone, though causing some local œdema, is more productive of general symptoms, which, commencing as irritation, twitching, and convulsions, finally end in paralysis; paralysis of the respiratory centre is especially characteristic. The globulin, on the contrary, incites a violent local reaction with hemorrhages around the point of injection, hemorrhages of the mucous membranes, and destruction of the coagulability of the blood. The latter phenomenon recalls to us the results of experiments performed on animals with pure peptones and albumoses of digestion. Kühne, Pollitzer, Schmidt-Mülheim, Shore, and Matthes found in a large number of these experiments not only characteristic hemorrhages and necroses, but also paralyses, the intensity of which was in correspondence with the higher hydrolysis of the albumoses.

You will perceive from what has been said that different cases of snake poisoning cannot have an identical course, and that the numerous contradictions of the mostly incomplete records of snake bites are to be explained only when we consider each type of poisoning separately. Leaving aside the cases of almost instantaneous death which are due to general thrombosis, especially when the venom has been accidentally injected into a large blood-vessel, we usually see about the following symptomatology. We will consider first the less complicated picture of the effects of a cobra bite: two small, scarcely visible punctures in the skin are found, whence radiates a burning and stinging pain with gradually extending œdema. Within an hour, on an average, the first constitutional symptoms appear —a pronounced vertigo, like that of drunkenness, quickly followed by weakness of the legs, which is increased to paraplegia, ptosis, falling of the lower jaw with paralysis of the tongue and epiglottis, inability to speak and swallow, with fully preserved sensorium. A mass of viscous, frothy saliva is constantly dribbling from the open mouth; nausea and vomiting set in; the paralysis becomes general, the patient lies motionless. The pulse, a little accelerated, is somewhat weaker in the beginning, but keeps a moderate strength until even a few minutes after the cessation of respiration. The latter, also accelerated in the beginning, soon becomes slower, labored, and more and more superficial, until it dies out almost imperceptibly. The pupils, somewhat contracted, react up to the last moment. Slight convulsions, which we are accustomed to see in asphyxia, sometimes occur shortly before death. Absorption is exceedingly rapid; already after thirty seconds a distinct areola is visible around the bite. Death occurs at the latest within fifteen hours, in thirty-two per cent. in the first three hours. When the patients do not die of paralysis, they recover remarkably quickly and without later consequences. The autopsy reveals no changes in the skin at the point of injection; the subcutaneous tissue, however, is thickly infiltrated with reddish serum; the surrounding blood-vessels are congested. All the in-

[1] Experiments carried out by Dr. A. V. Moschcowitz with sterile snake poison have demonstrated that it liquefies gelatin like some digestive ferments, *e.g.*, trypsin. Wehrmann (Annales Pasteur, 1898) finds that it peptonizes fibrin weakly and does not saccharify amylum.

[2] It is well known that albumoses, the products of the hydration of albumin formerly called propeptones and accurately defined by Kühne and Chittenden in 1884, differ widely as to their toxicity. While our modern means do not allow yet a chemical differentiation of those albumoses generated by superheated steam, by gastric digestion, by bacilli, or—as in our case—by the parenchyma-cell of a gland, the varying reaction of the more sensitive living organism toward them demonstrates decisively their different nature.

[3] Gastric digestion does not influence snake poison; the action of the bile, however, and of the pancreatic juice destroys it.

ternal organs are hyperæmic, and the bronchi are filled with frothy mucus and perhaps with fluids which have been forced into the patient's throat. The blood is mostly liquid and dark.

After the bite of a rattlesnake the local disturbance is most pronounced: violent pains at the bleeding wound, hemorrhagic discoloration of its surroundings, and later also of more distant parts; bloody exudations on all the mucous membranes, nose, mouth, conjunctiva, and hæmaturia or rather hæmoglobinuria. Usually somewhat later than after cobra poisoning, but possibly within fifteen minutes, constitutional symptoms may develop, great prostration with nausea and vomiting. A continuous fall of blood pressure is noticed. Respiration, in the beginning accelerated, grows slow and stertorous. After a temporary increase of reflexes, which in susceptible animals and after large doses may rise to convulsions, opisthotonos, and tetanus, paresis supervenes, with paraplegia of the lower extremities, which progresses in an upward direction, ending in complete paralysis. Albuminuria appears after about six hours. In such a condition death may come inside of twelve hours. If the patient recovers from the paralysis, a septic fever may develop in consequence of the enormous and multiple hemorrhages, to which he may succumb after a lapse of time. Eventual recovery sets in very suddenly, even in the most desperate cases. Not rarely, however, suppurating wounds remain, which granulate poorly, break open repeatedly, and may lead later on to deep necrosis, even of the bones.[1] The autopsy shows a deep bloody infiltration at the bite, down into the necrotic muscles, hemorrhages of distant muscles, particularly of the intercostals; all serous membranes, chiefly the endocardium and the peritoneum, are completely covered by ecchymoses of all sizes; the lungs show subpleural ecchymoses and infarctions; the kidneys are hemorrhagic in the glomeruli and pelvis, and there is cloudy swelling of the epithelium of the canaliculi. Hemorrhages have been observed also in the serosa and in the substance of the central nervous system. The blood is fluid, and does not clot, even after a long time.

If it is permissible to illustrate and fix the symptoms, which I could but sketch roughly, in a well-known and familiar complex, I might call the sequelæ of a cobra bite an acute bulbar paralysis of the most furious and vehement type. Also for the second type, that of viper poisoning, we have an analogy in acute ascending spinal paralysis, the last stage of which exhibits alike bulbar symptoms and inhibition of respiration. We may remember here that the common ascending spinal paralysis is also ascribed to an infection. Yet, whereas in the two diseases named the development of the nervous symptoms is very gradual, and they may take years or at least weeks to advance to a fatal exitus, in snake poisoning the effect is almost instantaneous. It may, therefore, be considered as firmly established that snake venoms affect the motor ganglia of the anterior horns and chiefly the medulla oblongata. There exist records of few accurate microscopic examinations of all organs after snake poisoning. In general they resemble the changes which we are wont to find in all kinds of poisoning of whatever origin, especially by the toxins of zymotic diseases, *e.g.*, fatty degeneration of the liver with inflammation of the bile ducts, acute parenchymatous nephritis, disseminated pneumonic patches, etc. Of the pathological changes in the central nervous organs, which, to judge from the symptoms, we may expect to find, no reliable records have been published. I am glad to say, therefore, that several gentlemen of this city have been working up some cases of snake poisoning, and they will give us later an analysis of their investigations. In the mean time, I may be permitted to state the substance of the results as a pronounced affection of the ganglion cells throughout the central nervous system, especially in the medulla; the chromatic structure and cyto-reticulum have almost disappeared, as well as the dendrites; the nucleus and nucleolus are not affected.

The question, then, whether snake venom is a nerve or blood poison seems to be definitely settled: it is both. We have, however, in this connection to consider separately some remarkable phenomena in the blood and circulation. In like manner the multiple hemorrhages might point to a disturbance of the vasomotor centre, and some investigators ascribe them to an enormously increased diapedesis. Fresh poison added to blood in a test tube or administered hypodermically causes the blood corpuscles to swell and allows the hæmoglobin to escape into the plasma. The hæmoglobin itself is not changed, the spectrum remaining normal. Local application of poison to a capillary area incites a vigorous diapedesis, as some consider it, while others think it to be a real rupture of the capillary walls. The blood cells escape and are destroyed to such an extent that a few hours after the injection of poison but one-half of the normal blood corpuscles are counted. Finally, however—and this point has been creating a most lively discussion—the coagulability of the blood is materially influenced. Formerly it was an accepted dogma that cobra venom increased and viper venom inhibited clotting; recently, however, the investigations of Heidenschild, and more so the careful experiments of Martin, of Sydney, have cleared up the matter. It is true that viper venom has a more pronounced influence upon the circulation, yet the doses and the mode and the rapidity of introduction are matters of the greatest importance. As a rule coagulation is inhibited for a long period. A small dose injected intravenously causes a positive phase of coagulability of two or three minutes, which is followed by a negative phase of longer duration. A second larger injection brings on the same positive and a much longer negative phase. A third still larger injection, which is borne remarkably well, destroys coagulability for a long period. At the same time the leucocytes disappear almost entirely from the circulating blood; they are massed in the liver, lungs, and bone marrow, and reappear only when the blood regains its coagulability (or perhaps inversely). A hypodermic injection, and therefore the majority of all snake bites, acts in the same way as a small intravenous injection. Immediate introduction of a larger quantity of poison into a blood-vessel may cause a sudden complete clotting of the whole mass of blood, with the exception of that in the pulmonary veins and the left heart. Many contradictory reports of the blood pressure, sudden stoppage of respiration, etc., are explained by the sudden massive thrombosis. The immediate cause of coagulation is probably a nucleo-albumin, analogous to the fibrinogenic substance of Wooldridge, also a nucleo-albumin. It is not preformed in the venom, but, as Martin has it, is liberated instantaneously by the action of the poison from the stroma of the destroyed erythrocytes and the endothelium of the blood-vessels, and it brings on extensive thrombosis at one stroke.

Another important effect of snake venom is the loss of the germicidal property of the blood plasma. It is well known that most normal blood serum destroys micro-organisms, or at least retards their growth.

[1] It is remarkable that in some cases a periodical relapse of inflammation and suppuration of the old cicatrices is reported almost at the same time every year. Leon Stejneger, in "The Poisonous Snakes of North America," p. 353, relates the case of the draughtsman of the Smithsonian Institution. After a bite of a coral snake, swelling and inflammation of a finger with loss of the nail are said to have recurred in ten successive years almost to the date of the bite. A cure was finally effected by means of the herb Micania guacho.

Ewing, of Washington, was the first to show in 1894 that this faculty was annihilated in the blood of animals killed by crotalus poison, and Martin has confirmed it for the venom of the Australian black-snake. This explains both the well-known rapid putrefaction of the poisoned organs and the danger of subsequent decomposition of the extravasated blood and the resulting sepsis during convalescence. We can create a closer similarity of the two types of poison in an artificial way. Viper venom, when heated to 80° C., loses its intense action upon the circulation and approaches cobra venom in character. The Australian snakes occupy in this regard an intermediate position, for besides a prominent cobra effect they produce moderate hemorrhage and always hæmoglobinuria. Persons poisoned by the East Indian Bungarus exhibit sometimes a peculiar course of disease. Some cases cannot be distinguished from cobra poisoning, yet in others a certain chronicity of symptoms is seen, which can be compared only to the incubation period of infectious diseases. From two to six days may have elapsed after the bite without any symptoms, when unexpectedly a general debility sets in, with albuminuria and a sanious discharge from the eyes, nose, and rectum. The patient invariably succumbs within a short time.[1] A disproportionate swelling is to be noted in poisoning by the European viper; it sometimes extends over the whole body. The poison of the African viper, the puff-adder, acts in a stupefying manner from the very beginning; the animal stricken stands without motion or reaction, as if the whole cerebral cortex was eliminated; complete sensory and motor paraplegia ascends gradually with sharply defined limits. In briefly summarizing the mode of dying from snake poison we might say: Death occurring within a few minutes is due to general thrombosis; a patient who dies within twenty-four hours may succumb in the first hours to paralysis of the respiratory centre, later to general paralysis; lethal exitus later than this time, days or even weeks after the bite, may be the result of sepsis.

It may be appropriate now to say a few words about the relative dangerousness of a snake bite. Statistics cannot give us an adequate idea as regards this point. Not all cases are reported, and not all bites reported are those of venomous snakes. Moreover, chance plays an important rôle in the sequelæ, *e.g.*, in what condition was the snake when biting? Were one or both fangs deeply implanted, or was the skin merely scratched? How old and in what condition of health was the bitten individual? India, as is generally known, has the largest mortality from snake bites; this is easily explained by the enormous number of snakes, and these the most deadly of all, the cobras. Nevertheless, indolence and superstition of the population may increase the number of fatal accidents considerably. Those may be right who consider the smaller number of deaths in America and Australia as due to the greater intelligence of the people, because a rational treatment is instituted in time, especially the early application of a ligature. In default of reliable analyses, the only way to decide this point has been shown by Calmette to be that of comparative experiments. After carefully graded hypodermic injections to determine how much poison may kill a kilo of animal (mostly rabbits), the following table has been worked out:

1 gm. of cobra and aspis kills	4,000	kilo of	rabbit.
1 " hoplocephalus kills	3,450	"	"
1 " fer de lance and pseudophis kills	800	"	"
1 " Crotalus horridus kills	600	"	"
1 " Pelias berus kills	250	"	"

[1] These observations should be further confirmed, for the general impression given is that of ordinary wound infection with subsequent sepsis.

But even this method has not yet yielded undisputed results, for Martin claims for hoplocephalus 4,000 and for pseudophis 2,000 kilo. At any rate the toxicity of snake venom is exceedingly high. A comparison with the toxins of infectious diseases as calculated to this date shows that only that of diphtheria comes up to 4,000 kilos, toxopeptone to 3 kilos, and the albumose of anthrax to not more than 80 gm. Besides the high toxicity, it is also the extremely rapid absorption and consequent early appearance of grave symptoms which distinguish snake venom from other toxins.

Leaving out the most serious cases, *e.g.*, when both fangs, and especially those of a large tropical snake, have thrown their full dose of poison into the tissues, the prognosis is not so bad as is generally believed. Weir Mitchell gives the mortality of crotalus bites in one place as twenty-five per cent., in another as not more than twelve per cent.; that of the Australian snakes is said to be only seven per cent. It has been mentioned how quick an amelioration may set in even after the most serious nervous symptoms have preceded. This is undoubtedly a reason why so many remedies have gained the undeserved reputation of being a sure cure. Most of the patients would have recovered without them.

This leads me, then, to the treatment of snake bites. It is not my object to pass in review all the remedies recommended and used. It would take the whole evening merely to read a complete list of them. Besides the whole pharmacopœia of minerals, vegetables, and chemicals, there have been at all times all possible substances in use which had the temporary reputation of being infallible. Such an array of remedies has forever been the proof of our utter helplessness—an example which, to our regret, is not without parallel in other ailments. The object of treatment is fourfold: first, to prevent absorption of the poison; second, to destroy or neutralize it; third, to accelerate its elimination; fourth, to treat symptoms of imminent danger. If the wounded limb, *e.g.*, a finger, cannot be amputated quickly, at least the circulation should be checked or retarded by a ligature as practised since time immemorial. A ligature is applied as tight as possible, not only at one, but at two or three places; *e.g.*, when a finger has been bitten, round the finger itself, at the wrist, and at the elbow. The experienced Wall is so convinced of the advantages of Esmarch's bandage that he not only recommends every physician in India to have one in readiness, but wants to see it in every well-regulated household. The ligature is relaxed at intervals of some hours to prevent gangrene, but is applied again as soon as practicable.

It has been an often-recommended custom to suck the wound with the lips or to apply cups. The result of such a measure is at least doubtful, because of the finely punctured bites; the sucking ought to be preceded by a long scarification into the deeper tissues. It is still safer to excise a large area of these tissues or destroy them with the actual cautery. Wall, taught by long experience, recommends proceeding in the most ruthless manner. By these means the absorption of poison can be limited to a possible minimum so that that the system shall gain time to overcome the whole quantity at intervals. How reliable a good ligature may be is demonstrated by a case reported, in which the effect of a fatal dose was arrested for sixteen hours, but after the ligature was loosened death occurred within two hours.[1]

The next question is: Are we able to render innocuous the poison in the tissues surrounding the bite? This leads us to a whole series of specifics, which owe their reputation partly to old traditions, partly to experiments in the test tube. The majority of these spe-

[1] Weir Mitchell: Smithsonian Contribution, 1861, p. 3.

cifics, which, it is true, neutralize the poison in vitro after a shorter or longer period (carbolic acid, *e.g.*, only after twenty-four hours), destroy all tissues to such an extent that it seems preferable to apply the cautery. Even the much-praised permanganate of potassium, recommended especially by Lacerda, of Rio, has not fulfilled the high expectations, for neither locally applied in a one-per-cent. solution nor injected intravenously has it the elective faculty to single out snake venom for oxidation in presence of other proteids. One per cent. of chromic acid has gained somewhat of a reputation; it does not destroy the tissues simultaneously with the poison, but it merely makes them shrink. Calmette has frequently tested hypochlorite of lime in a solution of 1:60; he found both its local and repeated hypodermic application as well as its internal administration of good effect; not less so a one-per-cent. solution of chloride of gold as a local remedy.

Ammonia, extensively used internally and externally, is nothing but a stimulant. Feoktistow actually advises against it, because he thinks he has seen after its use increasing hemorrhages caused by higher blood pressure. Neither has alcohol any local effect as a coagulating medium; it is to be rated also as a mere stimulant. It has always met with appreciation on the part of the real or, more so, of the alleged victim. Indeed, the use of this infallible specific has often been carried to such an extent that it was impossible to decide whether the patient succumbed to snake venom or to an acute alcoholism. It is, moreover, a fact that intoxicated persons, when bitten in this state, have not proved to be better protected against snake bites than sober people; and the enormous doses which we often hear of as having been administered deserve nothing but condemnation.

If, then, the chances of neutralizing the poison *in loco* are limited, we may ask if we can hasten the excretion of the injurious substance. The kidneys are attacked to a greater or lesser degree by the poison, especially that of vipers; hence it is doubtful whether we should be permitted to increase their activity. The vicarious excretion by perspiration, stimulated by diaphoretics, has also had dubious results. It has been demonstrated, however, that part of the poison is excreted by the stomach. Alt, of Munich, found that alkaloids, chiefly morphine, after hypodermic use were excreted by the stomach almost to one-half of their amount. When he tried the same method for snake venom, it was discovered that the animals whose stomachs were washed out were saved, whereas the controls died; at the same time the washed-out fluid was again poisonous to other animals. Hence it is probable that the use of the stomach pump may be of good service. Those of you who have read a minute description of or have personally witnessed the snake-dance of the Moki and Zuñi Indians of Arizona, will remember that after the performance the dancers who are sometimes bitten by the snakes receive a potion prepared by the priests, which contains an emetic. Then the whole crowd stand around a certain part of the parapet to empty their stomachs freely. This custom has undoubtedly been sanctioned by long experience.

Finally to settle upon a definite method of rational treatment, it will be necessary to proceed in a regular clinical way, in order to find the proper indications for therapy. What are the prominent morbid changes which threaten life? Are they irremediable or are they transient? That they are not irremediable is proved by the many individuals who survive a snake bite in spite of the gravest symptoms. We have seen that the poison exerts, first, a hæmolytic action; second, a destructive influence upon the cells of the medulla. We know at present of no pharmaceutical remedy which will arrest either the escape of the hæmoglobin into the plasma or the rupture of the capillaries. Maragliano, in his experiments with the blood in infectious diseases, found that a globulicidal faculty had developed in the plasma (*i.e.*, that erythrocytes were easily dissolved in such blood), and that this probably depended upon a diminution of the proportion of salts in the plasma. If these results be directly applicable to our question, it is to be expected that the intravascular introduction of chloride of sodium would be of some value in desperate cases of hæmolysis. It is worth a trial not only in future experiments, but, on account of its relative innocuousness, in any case of fresh rattlesnake bite. The effective remedy, however, which we now possess will be spoken of in conjunction with the other groups of symptoms to which we proceed directly. These symptoms we have found to be due to the toxic action upon the central nervous system. The changes in the ganglion cells, the dissemination and disappearance of the Nissl granules, whatever this may mean, must be fully reparable, since, as we have seen, rehabilitation takes place rather suddenly. If we are not able, therefore, to re-establish their function immediately, could we not at least tide over the dangerous period of deep depression? One method suggests itself to a medical mind, *i.e.*, artificial respiration. The heart-beat ceases several minutes later than respiration, and in one experiment Fayrer succeeded in keeping up the circulation for eight hours longer by artificial respiration. Fayrer and Lauder Brunton strenuously recommend that it be continued not only for hours but for days, with or without a tracheal cannula. This advice seems to have fallen somewhat into oblivion, especially since Martin claims that in poisoning by Australian snakes he saw no good results from artificial respiration, death occurring in spite of it in fifteen minutes after the heart stopped. Notwithstanding some failures we are justified in trying it for an extended time, always keeping in mind that an abrupt change may set in in the most desperate cases.

In this connection we have to consider a remedy which even recently has been praised with certain persistency as a specific; I mean strychnine. First used by Pringle in Australia, it was tested in India, and in spite of the little encouraging reports was enthusiastically championed by Dr. Muller, of Sydney. He declared the failures were due to insufficient doses, and he began with a dose of at least 0.01 gm., repeated several times until slight tetanic symptoms appeared.[1]

Many cases in Australia have been treated with strychnine, and upon the advice of the government, Indian surgeons have also used it quite extensively. Nevertheless, the results are not so convincing that we could rely upon this drug as a specific. The experiments of Kanthack and Feoktistow were negative; interesting, however, is the latter's positive experiment that artificial tetanus brought on by strychnine was arrested by snake venom. Roux[2] states that tetanus antitoxin has a certain influence upon snake poison, but not inversely. Atropine has been recommended as a stimulant for the respiratory centre. I do not find many instances of its use recorded, but fail to see why it should not be resorted to as well as strychnine.

This prompts me to relate the few instances in which snake poison has been used therapeutically. Dr. Amaden, of Glens Falls, near Lake George, a country abounding in rattlers, cured a man aged twenty-

[1] The tolerance toward strychnine seems to be quite extraordinary in these cases: thus gr. $\frac{3}{5}$ was used in the case of a boy thirteen years of age within three and three quarter hours, gr. $\frac{1}{8}$ in five and one-half hours, gr. $\frac{1}{4}$ in four and one-half hours, gr. $1\frac{1}{6}$ in seven hours, gr. 4 in six days.

[2] Annales Pasteur, 1894.

five years with unmistakable tetanus by two injections of one drop of fresh rattlesnake poison. It should be mentioned that snake venom has been used in an unsystematic way for several other diseases, *e.g.*, yellow fever, of course without success. Recently it has been asserted that during the plague in India some successful inoculations of cobra poison ($\frac{1}{50}$ and $\frac{1}{25}$ ℥) were made, and that some similar experiments in monkeys gave equally good results. Later correspondence, however, is silent regarding these experiments.

The therapeutics of snake-bite were in this state of hopelessness when a few years ago Calmette, and almost simultaneously Fraser, of Edinburgh, surprised both the scientific and the lay world with an antivenomous serum. It is to serum therapy and immunization, as we shall presently see, that we have to look for the successful treatment of snake-bites.

Regarding this topic the question first arises: Are there animals, as often affirmed, which are immune to snake poison? In East India the mongoose, a kind of weasel, the deadly enemy of the cobra, has the reputation of immunity; and in Europe the droll, bristled hedgehog (Erinaceus europæus) is considered the natural destroyer of the viper. More accurate observers have shown that the mongoose owes its apparent immunity to a certain low susceptibility, but more to its agility, and that the hedgehog is partly protected by its spinous coat;[1] it possesses, however, a higher resistance to snake poison than other animals, and from my own investigations I might figure a resistance of about four times that of a rabbit of equal weight. A relative immunity toward various toxins is well known to exist in different animals. The poisonous snakes themselves possess a perfect immunity against their own poison,[2] the species with weaker poison a relative immunity toward those with stronger venom, and even the non-poisonous snakes enjoy a certain security against the bites of the poisonous ones.[3] This faculty is ascribed to internal secretion, to the incessant influx of toxin into the circulation. A discovery of Phisalix corroborates this theory:[4] he found in the common Tropidonatur natrix a supralabial gland without a duct, which contained a poisonous secretion. The king-snakes of our Southern States, which are the enemies and destroyers of our poisonous serpents, seem to enjoy a perfect immunity.[5]

The idea of immunization is by no means a modern one. Even in antiquity we hear of it, and among savage tribes of ancient and modern times, wherever poisonous snakes abound, attempts at protection against snake venom are made under various forms, sometimes connected with mystic ceremonies. The poison is either taken internally in the fresh state or parts of the dried poison glands are eaten (as practised in South Africa). A shepherd, immunized in this way, admitted that the dried gland of the cobra had an intoxicating effect, which he compared to that of Indian hemp, only that, whereas the latter lost its effect gradually, the action of the first was not impaired by habit. Or it is used as an inoculation (Serpa Pinto). Sometimes one of the reputed antidotes is employed, as, *e.g.*, the *curados de culebras* of Mexico employ a composite plant, Micania guacho.

Sewall, of Ann Arbor, Mich., was the first to introduce methodical inoculation of snake venom with the idea of immunization. His experiments, in which, by gradually increased doses, he made his pigeons secure against seven times the lethal dose of massasauga poison, were published in 1887. Calmette, director of the Pasteur Institute of Lille, France, after a series of failures succeeded in securing immunity and at the same time in elaborating a protective serum, antivenene, which, in spite of some weighty opposition, must be considered to-day as the only reliable antidote to the deadly action of snake poison. Calmette manufactures antivenene by inoculating with cobra venom or with a mixture of cobra, crotalus, viper, and hoplocephalus venoms, in both of which the hæmolytic agent has first been eliminated by heating to 80° C. The inoculation of horses has been carried on for three successive years. Antivenene acts as a full protective in a dose of from 5 to 20 c.c., when injected even one and one-half hours after the introduction of venom. A number of reports from different parts of the world attest the curative power of Calmette's antivenene: it has been used with beneficial effect in East India, in Egypt, Africa, and in the West Indies against the different serpents of those countries. Fraser, who worked independently of Calmette for six years[1] on the same subject, does not agree on all points with Calmette; in fact, the latter's statements have not been thoroughly confirmed by the Indian physicians and by Martin, of Sydney.[2] Not only has controversy arisen as to the curative value of antivenene, but also other questions have been stirred up in relation to the chemical and physiological action of toxin and antitoxin, which promise to be of the greatest importance in settling this vital problem of therapeutics. I cannot refrain from going into some details in the controversy.

First, it was objected that Calmette asserted his antivenene to be equally effective against all kinds of venom, in direct opposition to Behring's law, that every toxin requires a specific antitoxin. It should be noticed that Calmette's horses are immunized with a venom in which the hæmolytic element has been destroyed. Hence while he may work out an antitoxin to the more important constituent, the nerve poison, he neglects the other agent entirely. Nevertheless, experiments seem to prove that the blood is acted upon as well.[3]

Another objection was made that the curative power was entirely overrated, since Calmette used as a test for estimating its value only the minimum test dose of poison. Fraser thus calculates that for a man weighing 60 kilos a dose of 330 c.c. of antivenene would be required—an amount which because of its bulk and its price would preclude its practical employment. Statistics and calculations do not, however, bear out this objection, for, with rare exceptions, not more than the lethal dose is injected by the snake in the average instance. At the same time, man has more resistance than the animals mostly experimented upon—a fact which may be considered an established law is that the larger the animal the less susceptible it is, weight for weight.

The discrepancies between the experience of Calmette and that of Martin, of Sydney, may probably be explained by the difference of Australian and Indian snake venom, so that an antivenene elaborated with Australian venom may have more curative power in Australia. It is less easy to account for the many failures of the Indian surgeons with the serum, although good reports are not lacking. An experimental investigation carried out by Semple and Lamb

[5] I have injected a king-snake (Ophibolus getulus) of Florida, of 700 gm. weight, with 1 gm. of fresh moccasin poison, a quantity which can never be injected by a single bite of the largest venomous snake. With the exception of a pronounced local swelling and some apparent sick feeling for a few days, the snake survived this experiment well.

[1] Fraser dries his antivenomous serum, in which state it is said to keep indefinitely.

at the medical school at Netley has also confirmed the value of antivenene.[1]

Another point of contest is the mode of action of the antivenene, whether it is chemical or physiological. Whereas Calmette with Roux and Buchner insists that antitoxin elicits or stimulates the resistance of tissues, Fraser and Martin assert with Behring that the action can be only chemical. The experiments with snake poison and its antidote point, in my opinion, positively to chemical action. For instance, a certain amount of antivenene counteracts a minimal lethal dose when injected on separate points of the skin, whereas $\frac{1}{1000}$ of this quantity mixed with the venom in vitro and then injected has the same effect. An experiment which was negative in Calmette's laboratory, but has been decided positively by the accurate Martin, is the following: A certain amount of venom and antivenene mixed in vitro is injected without injurious consequences. Then the same mixture heated to 68° C. (a temperature which renders the antivenene inert, but not the venom) is injected, and acts as if no antivenene had been added. Only when the mixture is allowed to stand at least twenty minutes is the venom neutralized, and heating no longer arrests the effect of the antitoxin.

Fraser[2] recommends the introduction of antivenene into the bitten limb rather than into distant parts, and its administration in repeated doses instead of one large dose. Martin advocates intravenous injection because he thinks that, whereas venom is rapidly absorbed, antivenene, probably on account of its large molecular size, enters the circulation slowly; a recommendation which for that reason he extends also to the use of antitoxin in severe cases of diphtheria or tetanus.

A new light has apparently been shed upon this topic by the researches of Phisalix, of Paris, who, while experimenting exclusively with viper venom, has found many substances which exhibit a decided antitoxic action. First he discovered in the blood serum of eels a substance which, according to Mosso's researches, has a similar effect to that of snake venom, only that larger doses are required, and in the poison of the Japanese salamander ingredients which serve to immunize against viper venom. Still more surprising was the similar action of cholesterin, separated from biliary calculi and from carrots, or that of tyrosin, separated from bulbs of the well-known dahlia and also from mushrooms. All these bodies, partly of vegetable origin, had a decided immunizing effect against viper venom, and the blood serum of animals into which these substances had been injected had an exactly similar effect. Very likely we have to add to these many vegetable remedies which have had more or less established reputation as snake cures, as, *e.g.*, the before-mentioned Micania guacho. All these substances, however, are capable of raising the resisting-power of the organism but little above the minimal lethal dose of venom; they have no effect whatever when injected simultaneously with the poison, but if introduced at least twenty-four hours previously they create an immunity of some duration. It must be noted that all these substances are the highest final products of proteid metabolism. I must not forget to mention the similar antitoxic influence of the suprarenal glands, the administration of which is a therapeutic measure recently come into prominence; their cortical substance seems to be more efficacious, and it may be of interest to know that the guinea-pig, which is the animal most susceptible to snake venom, has almost no suprarenal cortex.[3] It is to be hoped that the action of these proteid substances may lead us to a definite solution of the relation between toxin and antitoxin; and snake poisons, as Martin points out, are particularly well adapted for these investigations. They have the great advantage of being less sensitive than other toxins to light and heat, and of being comparatively easy to obtain in a form which preserves a remarkably constant composition.

To sum up, then, the most commendable treatment would be:

One or several tight ligatures should be made above the wound, followed perhaps by deep scarifications; then injection of antivenene, if at hand. If the latter cannot be had, injections should be made of a solution of hypochlorite of lime, 1 to 60, at several points near the bite and elsewhere. Stimulation, if necessary, by either strychnine or atropine or alcohol; hypodermoclysis of physiological saline solution; lavage of the stomach; artificial respiration for hours; and, not least of all, continuous encouragement of the victim, for a deep mental prostration goes together with the physical depression of the nervous centres.

It affords me great pleasure to acknowledge at this place my obligation to Dr. T. M. Prudden for many courtesies bestowed during my studies on this subject.

The reports of Drs. James Ewing and Fred. R. Bailey regarding the changes in the central nervous organs are herewith appended. Both gentlemen were to take part in the discussion of this paper, but, having been prevented from being present, they sent in the following statements:

Dr. James Ewing: The changes in the ganglion cells of the rabbit into which was injected moccasin poison, I found by Nissl's stain to be of a somewhat specific type and of extreme grade. The appearance of the cells was that of general disintegration of chromatic bodies without marked loss of the total amount of the chromatic substance. The outlines of the Nissl bodies were completely obscured; the substances had been redeposited in finely granular form all over the cell body and even in the pericellular lymph space. In the majority of the large stichochromes neither formed bodies nor reticulum could be distinguished. It was evident that the lesions went much deeper than the chromatic substance, affecting the underlying cyto-reticulum, which was granular, disintegrated, in places completely destroyed. The nuclei were very opaque, and the nucleoli often swollen or subdivided. The dendrites were often irregular, shrunken, or detached. These changes constitute a true acute degeneration of the cell, in contradistinction to the simple disturbances of chromatic substance, which may be entirely physiological.

I think the changes which I found in this rabbit were the most violent in the whole list of conditions included in my experience with degeneration of ganglion cells.

Dr. Fred. R. Bailey: Rabbit No. 1; snake poison, rapid action. The cells showing changes were confined to the anterior horn of the spinal cord. Most of these cells are normal. A small number of cells present those modifications in their chromatic elements, which probably evidence the early stages of a beginning acute degeneration, *i.e.*, an increase in the granularity of the chromophilic bodies and a fraying out at their edges, with some distinct loss in chromatic substance. The cyto-reticulum is normal. The nucleus may be normal, or there may be an intensification of the surrounding membrane and a thickening of the strands of the nucleo-reticulum. A few cells are found in which there is much greater loss of chromatin, the cell bodies appearing extremely pale and no distinct chromophilic bodies being present.

Rabbit No. 2; snake poison, long action. The character of the lesion is the same as in the preceding, but much more advanced and involving a much greater number of cells. Changes were found in the cells of

[1] British Medical Journal, 1899, i.
[2] British Medical Journal, 1895, i.
[3] Myers: Lancet, 1898, i., ii.

the (1) cortex, (2) cerebellum, (3) olfactory lobe, mitral cells, (4) basal ganglia, (5) medullary nuclei, (6) anterior horn, and (7) spinal ganglia. The cells showing the most marked changes were the anterior-horn cells and the Purkinje cells and the mitral cells of the olfactory lobe. The changes were those of later stages of acute degeneration.

Rabbit No. 3; heloderma,[1] rapid action. The changes were almost identical with those found in rabbit No. 1.

Technique: The material was placed in a four-per-cent. aqueous solution of formalin for twenty-four hours, then passed through graded alcohols. Sections were cut in celloidin and stained by Held's modification of the Nissl method, *i.e.*, erythrosin-methylene blue.

A FEW CASES OF EROSIONS OF THE STOMACH.

By EDWARD QUINTARD, M.D.,
NEW YORK.

Under the heading of "Gastritis ulcerosa chronica anachlorhydrica" in the *Archiv f. Verdauungs-Krankheiten*, vol. vi., No. 1, Dr. Luigi Sansoni, of Turin, describes three cases, the salient features of each of these being as follows:

When the stomachs of these patients were washed out during a fasting condition the wash-water was found to contain little pieces of mucous membrane, and furthermore it was found that after a test breakfast the gastric filtrate of such patients gave either a neutral reaction or else a very slight acidity. Again there was an absence of free hydrochloric acid and a negative or doubtful reaction in reference to lactic acid, but the motility of the stomach was good and in other respects the stomach was normal. From a consideration of the clinical facts above named, Dr. Sansoni comes to the conclusion that a constant presence of these pieces of superficial mucous membrane in the stomach washings existing along with a hypo- or anachlorhydria—cancer being excluded—significes a chronic superficial ulceration of the stomach, a condition which he would describe as "gastritis ulcerosa chronica anachlorhydrica."

In the Medical Record, June 23, 1894, Dr. Max Einhorn of this city, in a paper entitled "Clinical Observations on Erosions of the Stomach and their Treatment," described seven of these cases clinically. Previous to this, although such "hemorrhagic erosions" had been observed as a frequent anatomico-pathological occurrence, notably such investigators as R. Virchow, D. Gerhardt, O. Hartung, Langerhans, Ewald-Boas, Jaworski, and Korcynzski having called attention to them—yet to Einhorn belongs the credit of having first grouped these cases clinically, at the same time giving their history, symptoms, and treatment. Dr. Einhorn's paper was followed by very interesting ones on the subject. So far as we know these papers appeared in the following order: P. Cohnheim.[2] L. Sansoni,[3] Curt. Pariser,[4] Einhorn,[5] L. Sansoni.[6]

Let us refer briefly to Dr. Sansoni's first paper on the subject, a paper entitled "Sull' importanza diagnostica dei frammenti di mucosa gastrica estratti dallo stomaco digiuno." In this article Dr. Sansoni describes two cases in which he found small particles of mucosa in the stomach washings, one being the case of a young woman aged twenty-six years, the other that of a man aged forty-two. In both these cases ulcers were believed to exist. Furthermore these ulcers were supposed to have been the round or peptic ulcer in contradistinction to that more superficial solution of continuity known as erosion, for Dr. Sansoni distinctly says, in speaking of the case of the young woman aged twenty-six, after discussing whether it was an ulcer or an erosion: "Taking into consideration that the pain was circumscribed and that there were exacerbations of this pain after the ingestion of food, especially if it were irritating or coarse in its nature (wine, bread), the diagnosis of ulcer seemed to us the more rational, and as such it was treated." And again, in speaking of the man aged forty-two, Dr. Sansoni says: "The diagnosis of gastric ulcer is certain at least clinically." We wish to emphasize the fact that in these two cases it was evidently the round ulcer that was meant, as we wish to refer to this statement again. The study of these two cases leads Dr. Sansoni to conclude that "the finding of such pieces of mucosa is not only a symptom of mucous gastritis or of simple erosion of the stomach, as claimed by the authors above quoted, but in my opinion it has a still deeper significance in rendering probable a case of suspected ulcer, or in confirming a clinical diagnosis," ulcer in this case again evidently signifying the round or peptic variety of ulcer. Granting, however, that in these two cases there existed a round ulcer, which, after carefully reading their histories, does not appear to us at all certain, this by no means signifies that the finding of such small pieces of mucous membrane in the stomach washings speaks for ulcer. It would merely go to show that from time to time in the stomach washings of patients suffering from ulcer, as in the stomach washings of patients suffering from a variety of other pathological conditions of the stomach, we find fragments of the mucosa. But why Dr. Sansoni should have arrived at such a conclusion at all is what we fail to comprehend, because in Dr. Einhorn's paper, mentioned by Dr. Sansoni in this very article of his from which we quote, we are given a history of seven cases of erosions, in only one of which, and that a very doubtful case, was there even so much as a suspicion of ulcer; in fact they were proven distinctly to be not cases of ulcer, but of erosion. And here we ourselves must state as nearly as possible what we mean by the term erosion in contradistinction to the term ulcer. When hereafter in this article we speak of erosion we shall mean a superficial solution of continuity in the gastric mucous membrane, never extending as deep as the submucosa and whose edges never present the elevated indurated margins of that special form of ulceration frequently named, after the author who was the first to describe it graphically, the Cruveilhier ulcer, or, in other words, the round, peptic, or hyperpeptic ulcer. This statement must by no means be construed as implying that we mean that an ulceration and an erosion are two different processes pathologically, for unfortunately the etiology and pathology of such lesions are at present most vexed and undetermined. We use the terms as distinct in order to facilitate the clinical description of such cases.

When in the *Archiv für Verdauungs-Krankheiten* we come to read Dr. Sansoni's second paper on the subject, it must be confessed we are somewhat confused. For, in this last paper of his, we find before reading very far that what Dr. Sansoni now means by ulcer is something altogether different from what he meant in his first paper. For we will remember that in his first paper Dr. Sansoni, in reaching a diagnosis in the case of the young woman, says: "There was reason for the

[6] Archiv für Verdauungs-Krankheiten, Bd. vi., vol. i.

suspicion that at the very least there was a solution of continuity in the stomach, and hence an ulcer, or at least a simple erosion of the mucous membrane." Mark you, in Dr. Sansoni's mind at this particular time there was a distinction to be made between an ulcer and an erosion. Three years back when he spoke of ulcer he meant, as we have already shown, the peptic ulcer, and he did not apply the term of ulceration to erosion. Let us now see what he says in this second paper of his. After describing these cases in which fragments of mucosa were found in the stomach washings, he says: "Die constante Anwesenheit von Schleimhautstückchen im Wasser der im nüchternen Zustande vorgenommenen Magenausspülung mit Bestimmtheit für einen ulcerativen Process im Magen spricht. Ueber diesen Gegenstand bereitet jedoch Herr Poggio, ein Schüler der Klinik, eine Arbeit vor, in welcher er darthun wird, dass die mit dem Spülwasser aus dem Magen extrahierten Schleimhautstückchen nicht immer durch die Sonde losgelöst werden, wie manche behaupten, sondern in der Mehrzahl der Fälle in der Magenhöhle schon losgelöst vorkommen und wirklich eine Continuitätstrennung der Magenschleimhaut anzeigen." We quote in full because, in the first place, it shows that what Dr. Sansoni now means by ulcer is altogether different from what he meant three years previously, and in the second place to state that the hypothesis which his pupil Herr Poggio conceived, as regards the exfoliation of these small pieces of mucosa in these cases, is the same as was given by Dr. Einhorn in his original paper on the subject six years ago, the very title of which paper Dr. Sansoni, unfortunately for himself, seems to have forgotten, for we look all in vain for the name of the able clinician who first classified the cases clinically.

We learn, then, that Dr. Sansoni to all practical purposes has come to regard the terms erosion and ulceration as interconvertible. We shall not dispute his right to do so, and we really should think nothing more of the fact were it not for the last paragraph in this second article of his. We quote again: "Deshalb müsste man zwei Formen von chronischer ulceröser Gastritis unterscheiden: eine mit Hyperchlorhydrie und eine mit Hypo- oder Anachlorhydrie. Bei der ersteren liegt das typische Cruveilhier's che Geschwür vor, bei der letzteren handelt es sich um oberflächliche Ulcerationen, die meistens in Tiefe nicht über die Schleimhaut hinaus gehen, jedoch imponierende Hämatemesen und vielleicht auch Perforation herbeiführen können. Zu dieser letzteren Form dürften die von Dieulafoy unter dem Namen Exulceratio simplex beschriebenen Fälle, die hämorrhagischen Erosionen, wahrscheinlich viele der von den Autoren beschriebenen Fälle von Magengeschwür mit Hypo- oder Anachlorhydrie und die von mir beschriebenen drei Fälle gehören, welche letzteren, wenn sie durch weitere Untersuchungen besonders in anatomischer Hinsicht bestätigt werden sollten, eine besondere Bedeutung haben dürften. Denn auf Grund der bei ihnen angetroffenen objectiven Symptome, nämlich: 1. constantes Vorhandensein von dünnen Magenschleimhautstückchen im Wasser der im nüchternen Zustande vorgenommenen Magenausspülung; 2. nicht an eine Geschwulst in der Magengegend und Krebskachexie gebundene Hypo- oder Anachlorhydrie, wäre eine Diagnosticierung der Krankheit intra vitam möglich, während sie bisher erst bei der Autopsie gemacht wurde. Diese Form verdient wirklich den Namen Gastritis ulcerosa chronica anachlorhydrica." Let us take the last part of this paragraph first. We have just seen that Dr. Sansoni uses the terms erosion and ulcer as interconvertible—in other words, what Dr. Einhorn and other investigators describe as erosions Dr. Sansoni describes as ulcers. So far so good; but why, pray, anachlorhydrica? What about the seven cases described in Dr. Einhorn's first article—article and author so unfortunately forgotten by Dr. Sansoni? Among the seven cases we find four with hypochlorhydria, two which might be termed normal, *i.e.*, total acidity = 60; and one of hyperchlorhydria. Again in Dr. Paul Cohnheim's cases—cases it is true viewed for the most part pathologically—yet of these cases in which fragments of mucosa were found in the wash water, seven presented a normal acidity, and six hyperacidity. Again, in the very able article by Dr. Curt. Pariser, "Ueber hemorrhagische Erosionen der Magenschleimhaut,"[1] an article as yet evidently unseen by Dr. Sansoni, in only one case was there hypo-acidity; in both others the acidity was normal. Finally, in Dr. Einhorn's last report, we find among sixteen cases one of hyperacidity, three of normal acidity, seven of hypo-acidity, and two of anacidity. Now, are we to suppose for an instant—and from what Dr. Sansoni says we judge that this is his idea—that in those cases in which we have hyperacidity we have to deal with the Cruveilhier ulcer, and that in the cases of hypo- or anacidity we are dealing with cases not of round ulcer but with a form of ulceration absolutely distinct, and to which the term "gastritis ulcerosa chronica anachlorhydrica" is scientifically applicable? We say emphatically, No! To begin with, from what we have said the term employed by Dr. Sansoni is, we believe, a manifest misconception of the case. We all know that the round ulcer from time to time appears without an accompanying hyperchlorhydria, and in the cases reported, when along with the finding of the fragments of mucosa there existed hyperacidity, in only one case, and that one reported by Dr. Paul Cohnheim, was there even a suspicion of a round ulcer. We see, then, that these fragments of mucosa in the wash water are found in patients when the secretion varies from that of hyper- to that of anacidity. This again leads us to repeat that the pathological etiology of the various forms of ulcerations and erosions met with in the stomach is as yet a matter of much controversy. It is quite impossible at present, it would seem, to say whether the forms of ulcerations and erosions described by Lainé, Dieulafoy, Nauwerk, Marfan, etc., are all one and the same lesion in different states of evolution, or the same lesion as seen under different pathological surroundings. What we can say, however, is this, that clinically there is a difference. In fact, we can probably say that ulcerative and eroding processes are met with under the following clinical aspects:

(1) The patients who suffer from tuberculosis (mostly in the terminal gastritis of such patients), puerperal eclampsia, alcoholic gastritis, atrophic cirrhosis, and uræmia. These cases, unless hæmatemesis or perforation supervenes, run as a rule without definite gastric symptoms, and for the most part have been described at autopsy.

(2) The patients who with no past history of stomach trouble suddenly develop a terrific hemorrhage, and at the operation or autopsy there may be found by careful search erosions so tiny that for the most part they are best seen by the aid of a magnifying lens. These little erosions, one to several in number, are very superficial and never reach the submucosa, the cause of the "hemorrhagie foudroyant" in these cases being the eroded arteriole running at the base of the erosion. This is the exulceratio simplex so beautifully and graphically described by the great clinician Dieulafoy.

(3) The round ulcer first described by Cruveilhier with, as a rule, its train of classical symptoms.

(4) Cases in which small pieces of the mucosa are found in the wash water, thus showing erosions, a definite clinical class first described by Einhorn.

[1] Medicinische Revue für interne Medicin und Therapie, Wien, April, 1897.

(5) Primary ulcers from known specific and constitutional infections, such as tuberculosis, syphilis, etc. These ulcers run a varying course.

(6) Ulcers appearing after serious burns of the skin. These are for the most part intestinal and present very few gastric symptoms, the general lesion masking the same.

(7) Ulcers due to irritant chemical poisons, carbolic acid, etc.

As the following cases of erosions of the stomach came under my personal observation, and as the subject is quite new, it will be of interest to report them in full:

Case I.—October, 1897. R. H. M——, aged thirty-five years, machinist, of good habits and temperate. For the last eighteen months he has not chewed tobacco, but previous to this he used five packages a week. He has naso-pharyngeal catarrh. He has complained of gastric troubles for the past three years, and has a bad taste in the mouth all the time. He feels bloated and full after eating. There are slight pains after meals, but the quality of food makes no material difference. He has no dizzy attacks. The bowels are constipated. For the past four or five months there has been an exacerbation of these symptoms, and the patient has lost several pounds in weight.

Status præsens: The patient is somewhat pale and pinched. The tongue is very slightly coated. The thoracic organs are normal. There is some pain on pressure over the epigastrium. A splashing sound is heard just below the navel.

Examination, October 7, 1897, in fasting condition: The wash water contains mucus, and entangled in the mucus are two small pieces of pale gastric mucosa (examined microscopically) and one loose piece. The wash water is slightly tinged with blood.

October 8th: Practically the same results, and three pieces of gastric mucosa; the water is slightly tinged with blood. Later gave test breakfast, Ewald-Boas. Result: hydrochloric acid, total acidity 40; no lactic acid. The stomach was washed with warm water and sprayed with nitrate-of-silver solution 2 : 1,000, using the Einhorn atomizer.

October 10th: After test breakfast, Ewald-Boas, hydrochloric acid, total acidity 40. The wash water contains mucus, but no particles of mucosa.

October 12th: The wash water contains some mucus, but no fragments of mucosa. The stomach was sprayed with 2 : 1,000 nitrate of silver. From this time on the patient felt much better. He gained in weight several pounds, but the belching and the fulness continuing, probably owing to the slightly atonic condition of the stomach, cold ablutions, bitter tonics, and exercises were ordered with most beneficial results.

Case II.—J. O——, 1897–99, man aged forty-seven years, a chronic drinker for years. In this case Dr. Einhorn was called in consultation, and the patient's condition is described under No. 6 of his last series of cases. The following facts were interesting in this patient's case: A prolonged or desperate drinking-bout invariably ended in an acute attack of gastritis. Such an attack would last from three days to one week before the symptoms would subside. As a rule gastric lavage was practised during these acute attacks, and although mucus was always found in the wash water, mucosa fragments were not always present. Once, however, just as Dr. Einhorn and myself had gotten this patient in a very fair condition—in other words, just after he had been treated for erosions and to all appearances had been cured—he again indulged in large quantities of alcohol, with the result that the mucosa fragments appeared the next day in the wash water. It was interesting to note that whenever such pieces of mucosa were found in the wash water the patient's symptoms were more aggravated than at any other time. He would begin to lose weight, and his face became pinched and at times quite haggard; he would complain that his food hurt him, of great weakness on exertion, and he would become much more nervous. Finally, whenever the special symptoms described manifested themselves, we would wash out his stomach, with the result that we would find one to three tiny pieces of mucosa in the wash water. These symptoms extended over a period of several years, with intervals of several weeks between them, and at times when the patient had abstained several weeks from alcohol; yet it must be remarked that this patient, as a rule, no sooner was made better than he again succumbed to the desire for drink, and this left his gastric mucous membrane in a more or less constant state of inflammation. The gastric spray of 2 : 1,000 nitrate-of-silver solution, combined with proper diet and hydrotherapeutic measures, always resulted in a cure so far as the erosion went. Another peculiarity was that the total acidity of this patient's gastric filtrate varied greatly from time to time. As a rule it was about 47–50, but at times as low as 30 and again as high as 80, the hydrochloric acid being always present. The blood never registered below 80 H.; and as a rule registered between 85 and 90. In other respects there was absolutely nothing abnormal. The urine at times showed evidences of renal hyperæmia, *i.e.*, a trace of albumin and casts. The albumin and the casts appeared at times when the indican was in excess and when the normal ratio between urea and uric acid or between the mineral and ethereal sulphates was disturbed. The patient finally died following the effects of a prolonged debauch.

Case III.—May, 1898. J. A. H——, student, aged twenty-one years. He has complained for two years of gastric disturbances. He is a cigarette smoker and uses alcohol moderately. During the past six months symptoms have become worse. He complains that food hurts him, and that he feels weak; at times he has nausea, and if indiscreet in diet he vomits as a rule on the morning of the following day. He has lost considerably in weight during the past few months.

Status præsens: The patient is thin and pale, and his cheeks are somewhat hollow. The heart is irregular and somewhat forcible, what might be called a "smoker's heart." Lungs, liver, and spleen normal. There is some tenderness on pressure over epigastrium.

May 7th: Test breakfast, Ewald-Boas—total acidity 37, hydrochloric acid +; a good deal of mucus.

May 8th: Lavage in the fasting condition. Result: two pieces of mucous membrane in wash water. Spray, 2 : 1,000 nitrate of silver.

May 10th: Lavage in the fasting condition. One small fragment of mucosa and some mucus. Spray, 2 : 1,000.

May 11th: Lavage in the fasting condition. Some mucus, but no pieces of mucosa. No more fragments were observed, but as there was every evidence of chronic catarrhal gastritis the patient was treated for such and recovered.

Through the great courtesy of Dr. Alexander Lambert of this city, I have the following case to report:

Man, aged fifty-two years, merchant. He began to feel weak and lose flesh last January. He complains of a dull oppression back of the sternum. The pain did not seem to be increased particularly after eating, but it was worse after exertion, and again the pain seemed worse after eating if the patient had been tired just before.

Status præsens: The patient is slightly anæmic. The lungs are normal. The heart is slightly enlarged toward the left, but nothing more than exercise would account for. There is a slight increase of the second aortic sound with a slight systolic murmur at the aortic area. The urine is normal, with a normal amount of

urea. A week later a double murmur was found at the aortic area, which showed he had atheroma of the valves. He was given potassium iodide gr. v. t.i.d., and also general tonics. The patient did only fairly well, his heart sound became much better, the diastolic murmur disappearing entirely and only a very faint systolic remaining, and the exaggerated snap of the valves being much less marked. His general strength and his anæmia were better, but he was losing flesh, and his pain back of the sternum persisted. Under bitter tonics and nux the symptoms improved somewhat, but by no means disappeared. The patient still felt weak, and the pains still persisting back of the sternum, and the patient not having regained his weight, a carcinoma was suspected, and an Ewald-Boas test breakfast was given and expressed an hour and a half afterward. The result of the chemical analysis was as follows: Free hydrochloric acid absent; combined hydrochloric acid, 0.0548 per cent.; organic acid and acid salts, 0.0730 per cent.; total acidity, 0.1278 per cent. Lactic acid (Boas test) presented strong reaction. This was followed by lavage. In the wash water were found three small pieces of gastric mucous membrane, which being sent to Dr. Harlow Brooks were on examination found to be absolutely normal. After this the stomach was washed out every other day for four days with a dilute soda solution. At the end of ten days another test was given, the chemical report being: Total acidity, 0.264 per cent.; total hydrochloric acid, 0.085 per cent.; combined hydrochloric acid, 0.080 per cent.; organic acid and salts, 0.090 per cent.; trace of lactic acid. At this date the patient felt much improved; the pain was less, he felt much stronger, and there were no fragments of mucosa found in the wash water.

June 8th: The patient returned with some of his old symptoms. He feels weak, and suffers some pain and discomfort back of the sternum. His stomach was washed out and there were found three pieces of mucosa. The stomach was sprayed with a solution of nitrate of silver.

June 11th: Two pieces of mucosa were found in the wash water. The stomach was again sprayed with nitrate of silver.

June 13th: The wash water contained one piece of mucosa. The treatment with nitrate of silver was continued.

June 15th: The wash water contains no pieces of gastric mucosa. The patient expresses himself as practically well.

These cases reported by me resemble in their principal points those described by Einhorn; that is to say, in these cases there were the loss of flesh, the pain after eating not very intense, the exhaustion on exertion, the pinched and more or less haggard look at times, and finally that which rendered the diagnosis positive, namely, the repeated finding in the wash water of little pieces of gastric mucosa. So far as treatment is concerned it would seem that excellent results are to be had with the solution of nitrate of silver of the strength of 2 : 1,000 or stronger, sprayed by means of an Einhorn atomizer, this being done every other day. In the cases reported it can be seen that after two or three applications of the nitrate-of-silver solution the fragments of mucosa, as a rule, ceased to appear in the wash water, and in conjunction with this the subjective symptoms and the general condition of the patient improved. In a recent conversation with Dr. Einhorn on the subject, he told me that of late he has been using with seemingly good results five grains of the extract of suprarenal gland, powdering the stomach with this amount while the latter organ was in the fasting condition.

Our conclusions, similar to those of Drs. Einhorn and Pariser, are as follows:

(1) That from time to time we see patients in whose stomach washings are repeatedly found small fragments of the gastric mucous membrane; on an average one to four of such pieces are found in a washing, their size varying from 2 to 7 cm. long and about 2 to 3 cm. wide; that the repeated finding of such pieces of mucosa in the wash water shows that we are dealing with a case of erosion.

(2) That such erosions occur under varying pathological conditions, and that as a consequence the functional signs vary accordingly.

(3) That the exact etiology and pathology of such erosions are at present not definitely known; that in the great majority of cases at least where such tiny fragments of mucous membrane are found in the wash water the patient gives a definite and peculiar clinical history distinct from that of round ulcer or from the exulceratio simplex described by Dieulafoy.

(4) That as a consequence these cases should be regarded as a distinct class clinically and treated as such.

THE RADICAL TREATMENT OF TUBERCULOSIS OF THE TESTIS.

By ALEXIS V. MOSCHCOWITZ, M.D.,

ADJUNCT ATTENDING SURGEON, MOUNT SINAI HOSPITAL, NEW YORK.

It is a well-recognized and universally accepted surgical rule that when dealing with cases of surgical tuberculosis a thorough and far-reaching removal is an essential which must under no consideration be overlooked. Whenever such a thorough removal is not feasible, either on account of the involvement of vital organs or on account of technical difficulties impossible to overcome, recurrence of the tuberculous process may be looked for with almost absolute certainty.

It would carry me far beyond the scope of this short communication to go into the details of the pathological anatomy of genital tuberculosis, but for a thorough understanding of my reasons for advocating a more radical procedure in the treatment of tuberculosis of the testicle, I may be permitted to recapitulate briefly so much of the pathological course and progress of this malady as goes to prove the correctness of this aim.

It has not as yet been definitely decided whether or not there can be a primary tuberculosis of the genital tract without the coexistence of a tuberculous focus in some other part of the body; suffice it to say, for the purposes of this paper, that we not infrequently see patients who consult us with that peculiar nodule in the epididymis which experience has taught us to recognize as tuberculosis. No matter whether this be a primary or secondary focus, the subsequent course of this nodule in the epididymis will be mainly as follows: in the course of a few days, or at the most a few weeks, the tubercle bacilli will be carried by the seminal secretion into the corresponding vas deferens and will infect this at first in its scrotal portion; in course of time the infection gradually but surely travels upward into the inguinal and abdominal portions, until the entire vas deferens up to the seminal vesicles is involved; very soon this is also infected and becomes tuberculous. The next step is the infection of the corresponding lobe of the prostate.

Up to this stage the tuberculosis has run an insidious and a more subacute or even chronic course, and has not as yet involved any of the vital organs. Unless early recognized and properly treated, the process may subsequently very readily extend to the posterior urethra and bladder, with secondary infection of one or both ureters and kidneys. The testicle itself is but rarely involved, and if so only by contiguity from the affected epididymis.

In exceptional instances the progress of the disease takes place in the opposite direction; that is, the primary focus is to be found in the seminal vesicle, while the disease involves only secondarily the vas deferens and epididymis, in a direction opposite to the one quoted.

If this progress and extension of the process of tuberculous epididymitis are borne in mind, it does not require very much argument to prove the futility of the procedure for its supposed cure—namely, castration below the inguinal ring, or castration combined with evulsion of a part of the intra-abdominal portion of the vas deferens, as recommended by Büngner,[1] which has, with very few exceptions, been the practice up to the present. I do not speak of the various palliative measures in use, which make pretence to be radical. No one, of course, will deny that castration alone may also be radical at the beginning of genital tuberculosis—that is, at that stage when the entire process is still confined exclusively to the epididymis; unfortunately, however, the disease is so insidious in its onset as to escape the attention of the affected individual at this stage. It is self-evident, therefore, that a method for more radical treatment is clearly indicated.

Authorities and men of experience differ very much regarding the extent of the procedure which may be termed radical. To my mind we can then only speak of radicality when we may be reasonably sure that we have removed every portion of the tuberculous tissue, so that there is no opportunity given for a subsequent development of new tuberculous foci. In view of what has been said, it is but natural to conclude that the radical treatment of tuberculous orchitis, so called, would have to include, besides extirpation of the testis, also extirpation of the entire vas deferens, together with the corresponding seminal vesicle. Of the various procedures possible, I take the liberty to recommend the following:

Castration is performed by the usual method and through the usual scroto-inguinal incision, with the exception that the vas deferens is primarily not divided at the level of the vessels, but is carefully isolated from the other structures of the spermatic cord and left in connection with the testicle; then as much of the vas deferens is pulled out of the inguinal canal as can be done without running the danger of tearing it off. After placing a ligature around it, it is divided, and the proximal end is carefully seared with a Paquelin cautery, so that in the subsequent manipulation no opportunity shall be given for any exuded material to infect the channel of the vas deferens, between the peritoneum and the bladder. After removal of the testicle the external incision is closed, with or without drainage, depending upon individual cases. The patient is then placed in the lithotomy position, a sound is introduced into the bladder to serve as a guide, and a curved incision is made in front of the anus, extending from one tuberosity of the ischium to the other—the so-called prerectal incision of Zuckerkandl, or, more preferably, Kocher's "pointed arch" incision; after division of the superficial and deep perineal fascia, and of the tendinous union between the bulbocavernosus muscle and the external sphincter of the anus, the urethra being held to the front by a blunt retractor, the space between the rectum and urethra is deepened by blunt dissection, until the levator ani, or more particularly its anterior portion, the so-called levator prostatæ, is reached. This is then divided by a pair of scissors, the divided muscle retracts, and the prostate and the diseased seminal vesicle are reached by the palpating finger. The finger of the left hand is now introduced into the rectum, and hooked over the upper border of the prostate; traction is exerted, and it is surprising how much of the prostate and seminal vesicle can thus be brought into view. Should this, however, be impossible on account of adhesions, the seminal vesicle may be grasped by a clamp and gentle traction and manipulation may then be made to liberate it further. Proceeding in this manner, the entire unruptured seminal vesicle and the remaining portion of the intra-abdominal part of the vas deferens are brought into view (that the entire vas deferens is being extirpated can be recognized by the attached ligature and the seared surface). The seminal vesicle and vas deferens are by this time attached only by the ejaculatory duct, which can be readily cut off. Tamponade of the wound, and possibly the insertion of one or two sutures into each angle of the perineal incision, terminate the operation.

I have had occasion to operate on but one case by this method, and must confess that at the time of the operation it was unknown to me that other surgeons had operated by similar methods. Though the duration of the operation was somewhat prolonged, because of its novelty to me, I was very much impressed, not only by its feasibility, but particularly by the ease with which the extirpation of the seminal vesicle can be effected by this method.

B. W——, thirty-five years of age, married, a native of Roumania, barkeeper by occupation, was admitted to Mt. Sinai Hospital on August 18, 1899. There was no history of hereditary tuberculosis; he denies lues, but confesses to potus. The patient complains since four months of pain in the left testicle, at which time he also noticed a small nodule, which gradually became larger and harder; there was pain also in the left groin. He had no sexual impairment. There was considerable loss of flesh and strength. Physical examination led me to suspect the integrity of the left lung, but there were no definite symptoms of a tuberculous affection. The left testicle was of normal size and consistence; within the epididymis a hard nodular tumor was found, about the size of a walnut, painful on pressure, but not markedly tender; the vas deferens could be distinctly traced up to the inguinal ring, firmer than normal, and about the thickness of a small pencil. Rectal examination showed the left seminal vesicle to be the size of a thumb, and bulging nipple-like into the rectum. The genital organs of the right side were normal. The examination of the sputum and of the expressed secretion from the seminal vesicle and prostate gland for tubercle bacilli proved negative.

Operation was done on August 22d, under chloroform narcosis. An incision was made in the left inguinal region, extending a short distance downward upon the scrotum. As the patient was averse to losing the testicle, and as at the time of the operation it appeared to be perfectly healthy, I contented myself with the extirpation of the epididymis. In other respects the operation was finished as above described, Kocher's prerectal incision being used. It is to be regretted that, possibly through inadvertence, the sound introduced as a guide into the bladder was during the operation found to have perforated the urethra; the rent, however, was immediately sutured, and a permanent catheter was introduced into the bladder. The duration of the entire operation was one hour and fifty minutes.

Dr. Mandlebaum, pathologist to the hospital, was good enough to examine microscopically the specimens, and confirmed the clinical diagnosis of tuberculosis of the extirpated parts in every respect.

The subsequent course was uneventful, marred only by persistent vomiting, due to a marked alcoholic gastritis. The patient was discharged five weeks later with a minute urinary fistula, which subsequently closed spontaneously. He presented himself to me in November of the same year for examination, entirely cured

as regards the local tuberculosis, but with well-marked symptoms of tuberculosis of the left apex, to which he succumbed four months later.

A research of the literature pertaining to the subject has shown to me that the extirpation of the seminal vesicles for tuberculosis has been carried out a limited number of times, viz.:

Ullmann[2] was the first surgeon to extirpate the seminal vesicle for tuberculosis. After having performed castration for right-sided tuberculous epididymitis, he was enabled to watch the progressive development of tuberculous vesiculitis; hence five weeks after the castration he extirpated through a Zuckerkandl incision the right seminal vesicle with the abdominal portion of the vas deferens, and also the affected left seminal vesicle, but not the left vas deferens; incidentally he also extirpated a pea-sized tuberculous abscess from the right prostate. The patient was discharged with a perineal urethral fistula, which, however, closed spontaneously.

Villeneuve, quoted by Guelliot[3] in a communication to the Congress for Advancement of Sciences, Marseilles, 1891, reports a case of extirpation of the epididymis, vas deferens, and seminal vesicle by an extensive incision in the inguinal region and pushing back the posterior layer of the peritoneum toward the median line.

Roux, of Lausanne,[4] reports two cases of extirpation of the seminal vesicle and vas deferens for tuberculosis, by a perineal incision similar to Wölfler's pararectal incision; after division of the pedicle of the seminal vesicle, he sutured the overlying structures, so as to avoid, if possible, the formation of a urinary fistula. One patient recovered, while the other died shortly afterward of tuberculous basilar meningitis.

Routier, quoted by Guelliot,[3] extirpated through a Kraske incision a tuberculous seminal vesicle, which caused compression of the rectum, and obtained a cure.

Schede[5] tells briefly of two cases of extirpation of the seminal vesicles for tuberculosis, with temporary resection of the sacrum by Rydygier's method, and obtained a complete cure in both cases. Incidentally he criticises Büngner's method of castration with evulsion of the vas deferens, as he believes that the vas deferens is more likely to tear off just at a weak tuberculous infiltration and not in healthy tissue.

Weir[6] relates a case of double castration and complete extirpation of the vesiculæ seminales and vasa deferentia for tuberculosis. On the right side, while he was trying to extirpate the seminal vesicle, apparently by Villeneuve's method, the peritoneum was torn, but was immediately sutured. The operation was finished by a prerectal incision. The patient was discharged with a urinary fistula, which closed spontaneously in seven weeks.

A. G. Gerster[7] extirpated at the Mount Sinai Hospital in 1894 a seminal vesicle for tuberculosis, through a Villeneuve incision, and obtained a good result. The patient died two years later of pulmonary phthisis.

Fenger[7] is reported to have extirpated the seminal vesicle and vas deferens for tuberculosis, together with a small abscess in the prostate, through a perineal incision after Roux. The patient was cured.

Guelliot[3] gives an excellent account of the surgery of the seminal vesicles and reports two cases of extirpation for tuberculosis. In the first case a complete cure was obtained by high castration and extirpation of the seminal vesicle, through a perineal incision which encircled the anus for about two-thirds of its circumference. In the second case, involving both sides, the following were the operative steps: (1) Castration on the right side; (2) incision and curettage of left epididymis; (3) extirpation of the right seminal vesicle by morcellement, through a perineal incision; (4) testicular prothesis. The patient retained a urinary fistula, and died two and a half months after the operation, of acute phthisis.

Moullin[8] reports two cases of excision of the seminal vesicle for tuberculosis through a perineal incision, and obtained a complete cure in both cases. The second case was complicated by a urinary fistula, which, however, closed spontaneously.

From these reported cases it will be seen that the seminal vesicle may be attacked surgically by three different methods: (1) By the inguinal route; (2) by the sacral route; (3) by the perineal route. A comparison of the three methods will, I believe, result very favorably for the perineal route, as it has certain undeniable advantages over the others, which cannot be underestimated. Operation by the inguinal route appears to me to be very difficult, and the extensive stripping off of and not impossible injury to the peritoneum cannot be an indifferent matter; furthermore, the extreme depth in which the operation has to be carried out bars an inspection and treatment of the possibly infected prostate. The sacral route in any of its numerous modifications, with or without resection, or by a parasacral incision, certainly does expose the parts in question in a most beautiful manner, but the operation and dissection are necessarily so extensive as not to be entirely devoid of complications and dangers. Finally, there remains only the perineal route, which, as already pointed out, is devoid of many if not all of the dangers inherent to the other methods, is comparatively simple and easy of execution, and exposes the parts in question in a perfect manner.

In the performance of this operation there may arise many circumstances which may necessitate slight modifications in the technique; but as by this method the parts are fully exposed, it is but proper to individualize. It may, for instance, not be necessary to extirpate the testicle (and there are some patients—for instance, as in the case above reported—who are averse to losing this organ, though it may have become unnecessary and not functionating, through the extirpation of its efferent duct), particularly when it is taken into consideration that the testis proper is involved but very late in the disease, and even then not by metastasis, but by contiguity from the epididymis. I can well see that in such cases it might be permissible to extirpate only the epididymis with the vas deferens and leave in place the testicle. When in doubt regarding the testicle, we may go one step further and bisect it, so as to bring its stroma to inspection. It is perhaps needless to add that in those cases in which the testicle is not extirpated, care must be taken not to injure the spermatic artery and veins within the cord, as in either instance the nutrition of the testicle will be so much impaired that its removal may become imperative.

A decided advantage of this operation is that it enables us to inspect and palpate the corresponding lobe of the prostate; a localized nodule within the substance of the gland may be extirpated; abscesses may be incised, curetted, and drained.

The advantages I therefore claim for this operation are its ready execution and the possibility of removing radically all the diseased tissues. The disadvantages of the operation are only such as can be readily overcome by any one versed in the general surgical rules of procedure. The only disadvantage inherent to the operation is the possibility of a urinary fistula arising through the division of the ejaculatory duct, but even this closes in a majority of instances spontaneously. The indications and contraindications for the operation are those generally observed and recommended for tuberculosis of the testicle.

Although at the time of the operation (August, 1899) it was unknown to me that a radical operation

for tuberculosis of the testicle had been attempted by the perineal route, it is far from me to claim the least bit of originality for this procedure; my only claim, if it can be honored by so dignified a name, is a slight improvement in its technique. In concluding, I would express the hope that this operation may be given a more extended trial than is vouchsafed me, with the limited genito-urinary service in the surgical division of my chief, Dr. A. G. Gerster, to whom also I am gratefully indebted for this case.

A CLINICAL STUDY OF THE LIVER AS A FACTOR IN ELIMINATION, AND IN THE PRODUCTION OF NEPHRITIS.[1]

BY GEORGE E. DAVIS, M.D.,
LAWRENCEBURG, KY.,
VICE-PRESIDENT OF THE KENTUCKY STATE MEDICAL SOCIETY

AT Maysville, in May, 1898, I presented a paper to this society entitled, "The Physiology of the Liver and the Rôle it Plays in Digestion and Nutrition." You may deem it strange that I make another inventory of the functions of the liver, and small wonder, when we remember the triteness of the text. If, however, there is a lack of interest manifested in paying our respects to so esteemed a friend, our indifference may be attributed not so much to a blunted sense of obligation for services rendered, but rather to our ignorance of the mysterious ways he works his wonders to perform.

Digestion, nutrition, and elimination constitute metabolism. Metabolism, therefore, comprises those natural functions and processes whereby living organisms maintain vitality and being, and resist the impressions of time and disease. Thus the dynamics of life, beginning with the cell, are the chemical and physical activities required in the transformation of energy, involved in the processes of digestion, nutrition, elimination, growth, reproduction, and heredity.

The simple cell, as well as the differentiated cell of the higher or complex organism, acting under normal conditions, has the capacity of responding to the presence of food material by appropriating it to its own growth and multiplication, and of oxygen by yielding to disintegration or waste. The primary and inherent function of all life is a constant change, produced by an affinity for such material as by addition constitutes nutrition or growth on the one hand, and, on the other, a similar affinity for oxygen, by which oxidation and disintegration are constantly taking place.[2]

Under these conditions the processes and functions are termed physiological. However, these cells, acting under abnormal circumstances, as the presence of micro-organisms, are capable of responding in an exaggerated manner in protecting themselves individually, or the organism of which they are a component, against the toxic influences of said micro-organisms. This capacity of the cells for increased activity under adverse circumstances is the vis medicatrix naturæ. Under such conditions the processes and functions are termed pathological.

Therefore, if we would discover the secrets of the doctrine of organic evolution and heredity, and understand the functions of the widely differentiated and closely co-ordinated cell collections composing the several organs of the body, we are admonished to study them in the light obtained from the observation of the functions of the simple cell, acting under physiological and pathological conditions.

The single cell is the simplest form of organized life. Its existence is perpetuated by its capacity for selecting and imbibing such material as is fit for its nutrition and growth and rejecting that which is detrimental. This constitutes cell-metabolism. The human body is an aggregation of these minute organized bodies or cells into a variety of forms or structures, each having some special function. The great structural differentiation attained by the human organism opens up new avenues for invasion by pathogenic agents; however, physiological division of labor has kept pace and provides special functions, not only to protect the organism from toxic influences, but to sustain and nourish it. This capacity of sustenance, of selection and rejection, of assimilation and elimination constitutes body-metabolism.

Therefore, the maintenance of the natural functions of animal life and its vital resistance to toxic agents, resulting either from pathogenic bacteria introduced from without, or from the retention of excrementitious products of tissue disintegration within, depends on the activity and efficiency of metabolism, or the processes involved in digestion, nutrition, and elimination.

The agents essential for normal metabolism in the development and nutrition of the blood and body tissues are wholesome food, pure water, and fresh air, and the proper mechanism of suitable organs not only to elaborate these agents, but to eliminate from the system the waste products evolved in their elaboration. The quality and quantity of the blood depend on the quality and quantity of the food material and air, and on the efficiency of the digestive, respiratory, and eliminative organs. The blood is the vehicle by which the food material, after it has been elaborated, is distributed to all the tissues. When wholesome food and pure air have been supplied and the digestive and respiratory mechanism has been normal, the blood truly is the life. But, as the blood is also the recipient of the waste products of disintegration, nature has provided special organs for the elimination of said waste products or other harmful agents that may have gained entrance into the circulation. The kidneys are specially constructed for the elimination of the waste products of disintegration from the blood, which, if retained, would poison the blood and, through it, all the tissues; and in this instance the blood becomes the death. And thus, in the blood, we note that life and death tread so close, their paths needs must touch.

The laws of physiology decree that the integrity and vitality of the body and its different organs, in the performance of their several functions, are dependent on proper blood supply, and in turn the blood supply is dependent on the proper functions of the organs involved in metabolism, and though elimination is the last step in metabolism it is not the least important.

I have purposely dwelt at some length on the different steps in metabolism in order to emphasize their mutual interdependence and the intimate relation between the digestive and eliminative organs. Proper elimination is dependent on proper nutrition, and proper nutrition is dependent on proper digestion. Anything that disturbs digestion will disturb nutrition, which in turn will pervert elimination; and whatever aids digestion favors nutrition and facilitates elimination.

[1] Read before the Kentucky State Medical Society, convened at Georgetown, May 9, 10, and 11, 1900.

[2] Journal of the American Medical Association, July 1, 1899.

Digestion, nutrition, and elimination constitute a cycle in physiology, and since digestion is the first step in this cycle, it is most liable to primary derangements and usually is the origin of faulty metabolism around the whole circle; though, on account of the intimate relation of these processes, the converse may occasionally prove true. The derangements of digestion explain the genesis of most derangements of elimination, both of an acute and of a chronic character, and affords a key to the study of their symptoms and treatment. The liver is the largest and most complex gland of our complex body, and since it is especially endowed with important metabolic functions I seek to establish its intimate relation as connecting-link between digestion and elimination.

In my Maysville paper,[1] after reviewing the physiology of the liver, I made the declaration, "that the liver is the most important digestive organ of the body," basing the claim, first, on its biliary function in preparing fats for absorption and digestion; and, again, while the stomach, pancreas, and intestines perform the primary digestion of proteids and carbohydrates, the liver performs the secondary digestion and elaboration of these materials; truly a most important function, for it has been shown by many reliable investigations that the normal products of primary digestion act as toxins, or foreign bodies, when introduced directly into the general circulation. With equal plausibility, however, I could have made the declaration that the liver, if not directly through the bile, is indirectly the most important eliminative organ in the body, if we are to accept the current teaching of the physiology of the liver in its capacity of transforming the products of disintegration and completing the retrograde change of the substances from non-diffusible colloids into crystalloid, dialyzable materials before they pass into the kidneys for final excretion. Many investigations, physiological and pathological, make it clear that the hepatic and renal functions are intimately connected, the chief object of the kidneys being to excrete certain products secreted by the liver. Urea is thus formed by the liver, which is returned to the blood to be finally eliminated by the kidneys. And since urea represents the greater portion of the nitrogen taken into the body in the way of food, therefore an analysis of the urine should be a good test of the hepatic condition. Urea, then, in a measure, constitutes a fair expression of the retrograde change in nitrogenous tissue metabolism and to that degree possesses definite clinical value.

Renal insufficiency, therefore, proclaims preceding hepatic insufficiency—disturbed nutrition and auto-intoxication intervening. Renal inadequacy, functional and organic, has its origin most frequently, if not invariably, in primary hepatic inadequacy in elaborating the products of both constructive and destructive metabolism. The kidneys first suffer functional disturbance because said imperfect products are brought to them in a form chemically unable to pass through them, organic change supervening as a result of the long-continued irritation occasioned by these incompleted products of metabolism. Especially is this liable to happen to those who indulge in over-feeding and lack of exercise, or overwork, mental and physical, producing excessive somatic change, and lack of fresh air, resulting in imperfect oxidation, which further embarrass the hepatic functions. Thus we can easily conceive how the blood, overloaded with food products imperfectly elaborated for nutrition and products of retrograde change, some of which are not completely reduced for elimination, will act as an irritant to the kidneys, finally producing nephritis with albuminuria —thus interfering with elimination and later resulting in auto-intoxication.

[1] Medical Record, September 17, 1898.

And need the hepatic origin of renal insufficiency and degeneration hardly tax our credulity when we remember the intimate relation of the liver through its nerve supply, sympathetic and spinal, not only with the digestive and eliminative organs, but also with the vital processes of respiration and circulation? Moreover, in view of said intimate relation of the hepatic functions with both the digestive and eliminative organs, we more nearly appreciate the prime importance of the liver in metabolism, and understand how the pathology of Bright's disease, with albuminuria, may be traced to hepatic derangements, which cause degeneration as a consequence of the long-continued elimination of products of faulty digestion, resulting from derangements of the nutritive and disintegrative processes in which the liver plays so important a part; and in many instances, if not all, the liver seems primarily at fault. Again, diabetes mellitus furnishes positive clinical evidence of faulty elimination of hepatic origin, and I need hardly remind you that saccharine urine is not due to any morbid condition of the kidneys. What I seek to emphasize is, that sugar in the urine indicates functional hepatic derangement. However, chronic degeneration of the kidneys, with albuminuria, may prove a sequel to diabetes as a consequence of the constant irritation of the saccharine urine.

The pathology of faulty renal elimination has its etiology, then, most often in primary functional derangements of the liver interfering with digestion, nutrition, and disintegration, but the deleterious effects of retained products of imperfect metabolism are manifested not only in derangements of the kidneys, but in derangements of the nervous system, in derangements of the organs of circulation and respiration, and in abnormal conditions of the skin, etc. Some of the remote effects of the functional derangements of the liver may be noted in impairment of the voice; as witness the recent retirement of Calve from the stage, on account of her liver, whose functional disturbance has jarred the tones of a voice instinct with melody divine —the world and art the losers.

The indications for treatment in renal insufficiency, then, are to aid digestion and nutrition and promote disintegration. A careful regulation of the diet and free supply of oxygen by fresh air are of the first importance. The former corrects digestion and nutrition, and the latter promotes disintegration. After these come cholagogues and alteratives, which favor digestion and promote disintegration. Often the best diuretic, aside from water, is the drug that touches the liver and arouses it to the performance of both its digestive and disintegrative functions.

The liver, primarily by its digestive functions in completing and perfecting the elaboration of the food materials for the development and nutrition of the blood and tissues, and secondly by transforming the waste products of disintegration into soluble or dialyzable forms for elimination, is the beginning and the end, the alpha and omega in the cycle of metabolism —constructive and destructive—embracing digestion, nutrition, and elimination.

With the presentation of the arguments I have briefly stated I submit the plausibility of my claims—"that the liver is the most important digestive organ of the body," and, "if not directly through the bile, indirectly through urea is the most important eliminative organ of the body."

Individual Communion Cups have been introduced into a Congregational church in Ipswich, England. Whether or not this hygienic innovation is a result of the recent meeting of the British Medical Association in Ipswich is not stated, but it is the first instance of the sort in England.

Asepsis in Obstetric Practice.—James U. Barnhill says that before the days of antiseptics the death rate in the Maternity Hospital of Paris from 1860 to 1864 was eleven per cent. In the New York Maternity Hospital, where antiseptics were first introduced, it was for the nine years preceding 1883 4.17 per cent. The great value of strict antisepsis in obstetrics is insisted upon, as is the necessity for observing all rules which apply to aseptic surgery. Rules for disinfection are indicated. It is suggested that societies follow the example of the obstetric section of the New York Academy and adopt resolutions to the effect that it is the duty of every obstetrician to surround the parturient woman confined in her home with the same safeguards against infection that are being used in hospitals.—*Annals of Gynecology and Pediatry*, August, 1900.

Tonsillar Obstruction in the Fauces and Pharynx.—A. W. Francis emphasizes the importance of early recognition and treatment of tonsillar affections. Prominent symptoms formerly attributed to the faucial tonsil are now known to be due to adenoid growths in the pharynx. The most important feature of these growths is the relation to deafness from mechanical pressure and frequent attacks of otitis. The main symptoms are a sensation of a foreign body or lump in the throat, frequent ineffectual efforts to swallow something beyond reach, sensation of constriction about the throat, globus hystericus, frequent "clearing of the voice," voice fatigue after moderate effort, evening hoarseness, ill-defined uneasiness in the throat, loud brassy cough at puberty, reflex nervous symptoms, palpitation of the heart, and spasmodic asthma. The treatment is surgical.—*Annals of Gynecology and Pediatry*, August, 1900.

Albuminuria in Young Men.—H. W. Syers claims that in the case of young men between the ages of fifteen and twenty or twenty-five years, albuminuria is often found which is not a symptom of renal disease. As albuminuria can be induced in perfectly healthy and robust individuals by exposure to cold, the author holds that many of these cases are due to chilling of the surface of the body, as in open-air bathing. Why albumin should appear more readily in the urine in some cases than in others in which the same exciting cause is present can be explained only on the same principle as the well-known tendency of some people to catarrh on the least exposure. When examination shows entire absence of the renal heart (hypertrophy of the left ventricle, reduplication of the first or accentuation of the entire second sound), a pulse of normal tension, and no œdema or dyspnœa, then, if there are no casts, it is in the highest degree probable that the kidneys are perfectly sound. Of course it is possible that if the patient is likely, from carelessness or necessity, to be repeatedly subjected to the chilling process, what is at first merely an ordinary stasis in the kidney might, by constant repetition, become a renal inflammation.—*The Clinical Journal*, August 1, 1900.

Psychoses Accompanying Chorea.—Krafft-Ebing divides the mental disturbances sometimes attending Sydenham's chorea as follows: (1) Elementary psychic disturbances. These are seldom wholly absent, and may be ascribed in part to the general neuropathy and the psychically irritating effect of the choreic movements and in part to direct stimulation of the diseased cortex. They comprise variability of temper, nightmares, evanescent visual hallucinations, etc. (2) Fleeting fever, delirium of light grade. (3) Symptoms of psychic fatigue evidenced by forgetfulness, impaired cerebration, lack of concentration, apathy, incoherence, deficient food absorption, fever, etc. (4) Psychoses in the stricter sense, originating from the same infectious source as the chorea, and presenting simple or hallucinatory confusion going on to stupor or dementia. (5) Complicating psychoses due to the same mental condition as the chorea or arising independently.—*Wiener klinische Rundschau*, July 29, 1900.

Gall Stones.—Dudley P. Allen reports ten cases and urges various considerations, the object being to establish the following three propositions: (1) That in cases of continued distress in the epigastrium, when a physician skilled in modern methods of investigation, both clinical and physical, can make no positive diagnosis and give no relief, an exploratory operation is advisable. How it is to be completed must depend upon what is found. (2) Operation under such conditions frequently results in the removal of gall stones, or the setting free of adhesions, and entirely relieving the patient's suffering. (3) Such operations should not be too long delayed, since the formation of dense adhesions, such as are found not infrequently, may greatly enhance the difficulty of operating and endanger the life of the patient.—*Cleveland Journal of Medicine*, August, 1900.

A Contribution to the Statistics and Treatment of Umbilical Infection.—Theodor Escherich regards it as of great importance in preventing infection in infants by way of the umbilical wound, that the cord be cut close to the body and only a very short stump left. A second point is the omission of the full bath until the stump has dropped off. In his experience no untoward results have been noted, and the chances of infection are lessened. A suitable covering for the stump is difficult to devise, especially for use in institutions in which time and expense are objects. It should be easily and quickly removable and cheap. A form he recommends consists of a square of gauze fastened around the body by a pair of tapes and kept from slipping out of place by a third band passing around the neck. For inspection and renewal of the dressing it is simply necessary to undo the lower tape, and the flap may be lifted, uncovering the whole umbilical region. If the stump is long in dropping off or does not desiccate as it normally should, it furnishes a most favorable medium for the growth and development of infectious organisms. Simple amputation of such a remnant leaves an open wound which is also dangerous; hence the author advises removal of the persistent portion of cord with the Paquelin cautery. This disposes of the offending tissue and also seals the wound, which receives a dry dressing of airol.—*Wiener klinische Rundschau*, July 29, 1900.

The Treatment of Necrotic Acne with Sea-Water.—Linthlen describes as acne necrotica a form characterized by a chronic course, frequent relapses, and the formation of a localized induration which eventually develops a dark-colored parchment-like crust lying on a level with the skin. If this be removed a loss of substance is revealed extending far into the corium and healing into a deeply sunken scar. Its most frequent site is on the face in the bearded region or at the junction of forehead and scalp, while its painfulness and the disfiguring scars produced make it a really serious trouble. None of the remedies generally recommended is useful for this form, and the author, prompted by the observation of one of his patients that his lesion always receded in summer when he bathed frequently in the ocean, made the experiment of trying sea-water as a local application. Compresses saturated with a one-half-per-cent. solution of the sea-salt of commerce was left on over night, and by day a lanolin ointment of the same strength was applied. The results were most satisfactory; the necrosis was promptly checked, healing of the existing

lesions was promoted, and the formation of new ones apparently permanently prevented.—*Wiener klinische Wochenschrift*, August 2, 1900.

The Abortive Treatment of Bubo.—H. M. Christian says two methods claim attention, the abortive and the operative. Too little attention is paid to counter-irritation and pressure as a means of averting a cutting operation. It must be applied early before pus is present. It is useless to attempt to abort a tuberculous adenitis. Thirty to forty drops of a two-per-cent. carbolic-acid solution may be injected into the gland, or two syringefuls of a one-per-cent. solution of benzoate of mercury with sodium chloride 3:1,000 added. The best results are obtained at the Philadelphia Polyclinic by the application of equal parts of mercurial and belladonna ointments, lanolin and ichthyol, and a spica bandage.—*Therapeutic Gazette*, August, 1900.

Double Heart Beat.—G. D. Giuranna says that a duplicated beat is produced by an abnormal, supernumerary beat, which may be diastolic or systolic. (I.) When diastolic, it may be due to an exaggerated wave owing to overfilling of the ventricles. In mitral stenosis it may occur because of the increased force with which the blood descends at the beginning of diastole of the left heart, the left side being overfilled and the ventricle drawing in the blood with greater energy. In aortic insufficiency the blood regurgitates with abnormal force into the left ventricle, striking against the walls of the ventricle and raising the internal pressure. Double diastolic beat may in mitral stenosis be the expression of an exaggerated systole of the auricle, in which case it will be presystolic. (II.) When systolic, the double beat may be due to low arterial tension in proportion to the systolic energy of the ventricle, the simple muscular contractions which form the wave not blending as harmoniously as usual. This form of double beat is produced in the second period of systole.—*Giornale Internazionale delle Scienze Mediche*, July 31, 1900.

Ocular Headaches.—W. A. Brailey says that while the great majority of headaches are of course independent of the eyes, it is a matter of general acceptance that ocular errors produce headaches, though by no means in all cases. Muscular errors are the most important class concerned in their production. Accommodative movements are bound up with a great number of ocular headaches. As a general rule, the larger the ocular error the less the effect produced on the head, the reason being that a great defect of accommodative power leads to its abandonment, the patient seeing as best he can without it. Low degrees of hypermetropia and hypermetropic astigmatism are often causes of headache; so is a moderate inequality of refraction, especially if astigmatic. Another potent factor in headaches is the tendency to binocular vision, and here we have another rule: the stronger the tendency to binocular vision the more headache produced by an error of the recti and obliqui muscles. Ocular headaches are most frequent between the ages of ten and forty-five years; women are the greatest sufferers, and Americans appear to be more affected than the English.—*The Medical Press*, August 15, 1900.

The Treatment of Hay Fever.—E. B. Gleason says that Bishop has called attention to the fact that the neurotic condition of the patient and the hypersensitiveness of the nasal passages are often due to an excess of uric acid in the blood. Horsford's acid phosphates in one-half to teaspoonful doses in a tumbler of water at each meal gave very satisfactory results. The author has prescribed nitro-muriatic acid in doses of three to five drops of the freshly prepared concentrated acid after meals, and sometimes also at night. The dose should be diluted with a half-tumblerful of water, and the patient, after taking the medicine, should rinse out his mouth and swallow another half-tumblerful of water. The hay-fever symptoms are usually relieved in forty-eight hours, but not a single dose must be omitted, or some symptoms will return. Hyperæsthetic areas upon the respiratory portion of the nasal mucous membrane should be touched with a ten-per-cent. solution of chromic acid, after cocainizing the nose. Temporary relief may be obtained during the worst stages of the attack by spraying the nose with a weak alkaline one-per-cent. solution of cocaine, and afterward with fluid vaseline as a protective. Good results have been reported from the local use of a ten-per-cent. solution of the extract of suprarenal capsule.—*International Medical Magazine*, August, 1900.

The Treatment of Epilepsy by Fleisig's Method.—J. Séglas and Heitz subjected twenty-two patients to this treatment, which consists in first administering opium in progressive doses (up to 1 gm. daily on the twelfth day) for six weeks, and then replacing it by potassium bromide 7 gm. a day, gradually diminished to 2 gm. The authors believe that only a limited number of patients can bear this treatment. Its administration requires such care and such constant supervision that the patient must be placed where he can be under observation; even under these conditions the treatment is difficult and even dangerous. These drawbacks are far from being compensated by the advantages of the method, and the authors much prefer the simple bromide treatment.—*Archives de Neurologie*, August, 1900.

Prophylaxis in Malaria, by Protection from Mosquitos.—Eugenio di Mattei reports the result of an experiment carried out upon five persons, himself and four workmen. A hut situated in an extremely malarial region, infested by mosquitos, was chosen, and here the five slept for thirty-two nights. Their work during the day was arduous, their food scanty, their accommodations were uncomfortable; they took no quinine or other medicament, but their hut was so completely protected by wire gauze that no mosquitos were able to obtain access. No one of the five contracted malaria, although other workmen, sleeping in the neighborhood and unprotected from the mosquitos, suffered from grave forms of the disease.—*Archivio per le Scienze Mediche*, vol. xxiv., No. 2, 1900.

Toxic Paralysis of the Pharynx.—Patrick Watson Williams says that, excluding the purely myopathic paralyses, toxic paralyses are due to inflammatory degeneration of the neuron, that is, in its wider sense, neuritis, and may be divided into two distinct pathogenic groups: (1) Infective neuritis, commonly occurring in the course of diphtheria, less frequently observed in typhoid, typhus, scarlatina, morbilli, influenza, rheumatism, tuberculosis, syphilis, and pneumonia; (2) toxic neuritis, most frequently due to lead poisoning, but also reported to have occurred in poisoning by arsenic, copper, antimony, phosphorus, alcohol, atropine, and morphine. The treatment of these toxic laryngeal paralyses may be thus summed up: (*a*) appropriate general treatment of the infective disease, and measures directed to removal of the poison in the circulation and tissues in the case of organic or metallic poisons; (*b*) intra-laryngeal applications of the faradic or galvanic current, combined with the internal exhibition of strychnine in considerable doses either by the mouth, or directly into the affected muscles when feasible; (*c*) the relief of dyspnœa and threatened asphyxia in cases of bilateral abductor paralysis by intubation or tracheotomy.—*The Medical Press*, August 15, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, September 15, 1900.

PERFORATING ULCER OF THE STOMACH.

THE history of modern operative experience with perforated ulcer of the stomach is comparatively short; in fact, it is only within the last eight or nine years that successful cases have been recorded. Finney, in the *Annals of Surgery*, July, 1900, has a paper in which there is a general review of the subject with a collection of cases gathered from the most recent medical literature, bringing the total of reported operations up to nearly three hundred. There is also given a comprehensive analysis of the statistics of the subject, many of which are interesting, though perhaps not very novel. According to various authors the frequency of perforation is estimated at from 6.5 per cent. to eighteen per cent. of all cases of gastric ulcer, pretty wide variations, with the chances of accuracy, we should say, in favor of the smaller figure. The most important factors in the pathological anatomy of the condition are the presence of adhesions and the location of the perforation. A large majority of ulcers are situated upon the posterior wall of the stomach, but in this region comparatively very few of them perforate, while the converse is true in regard to those upon the anterior aspect of the organ. The presence of adhesions of course modifies the symptoms and prognosis, when perforation occurs, in ways which at once suggest themselves. In about one-fifth of all cases of perforated ulcer, it is important to remember that the perforation is multiple, so that in operating we should always be on the lookout for such a state of affairs.

Most general interest on this subject naturally attaches to the question of symptoms and treatment, and in many ways our knowledge has made important advances in the last few years. When an intelligent history can be obtained, and when the patient is seen early, the diagnosis is often easy, but under other circumstances we may have to be satisfied with the conclusion that we are dealing with a grave abdominal lesion, and allow our incision to disclose exactly what has occurred. Many cases of perforation have been observed in women before the age of thirty, while when men are the victims the condition occurs most often after forty; but ulcer of the stomach is absolutely much more frequent in women than in men. The physical signs, it is hardly necessary to say, are those of air and fluid in the peritoneal cavity and later the signs of general peritonitis. A history of previous gastric troubles of various kinds can be elicited in nearly all cases, and is useful as confirmatory evidence.

The treatment of the condition, though it involves some questions which are not answered by all in precisely the same way, is of course entirely surgical. Whether to use opium or morphine is one such question, the answer to which is probably best given by advocating a middle course, always keeping in mind the objections to the use of such drugs in patients who must undergo severe abdominal operations. Finney's conclusion is undoubtedly just, that nothing is to be gained by waiting for the disappearance or amelioration of the shock which is usually present for some time after the perforation has taken place, but we should also emphasize the fact that at the same time every possible means for combating shock should be used. A point noted by some writers with words of commendation is the use of cocaine anæsthesia in some cases of this class. Those who have used it will be satisfied with it and will often feel that one source of danger to a patient, almost always in a desperate condition, has been avoided. This method deserves more attention than it usually gets, for the risks of ether or chloroform anæsthesia in patients with dangerous abdominal conditions, often accompanied by much distention, is either not appreciated or too often disregarded. The incision to reach a supposed perforation of the stomach is almost always in the middle line of the epigastrium, and need not at first be very extensive, though enlargement may be necessary, and, when a perforation is found, the plan which can be carried out with the greatest celerity consistent with safety is the one which should be adopted. The abdominal cavity must be thoroughly cleansed and all foreign material carefully removed. The question of drainage will usually have to be decided according to the apparent requirements of each case. When we are dealing with a perforated gastric ulcer, the most important point to remember is that the patient's chances of recovery are diminishing at the rate of about eight per cent. an hour from the occurrence of perforation to the time of operation (unless we are dealing with a case in which protective adhesions are present), so that the indication for immediate radical treatment is peremptory.

A FATAL CASE OF EXOPHTHALMIC GOITRE.

ALTHOUGH it is not uncommon for exophthalmic goitre to set in abruptly, especially after psychical or physical shock, and while at times the symptoms may attain a profound degree of intensity, a fatal issue is quite rare. It is in fact rather remarkable that the results of more autopsies have not been placed on record, and although exophthalmic goitre is not an exceptional disease it does not often figure in the death lists. The disease is further most common at or about the thirtieth year of life. In view of the foregoing considerations a case of exophthalmic goitre in a girl eleven years old, reported by Armstrong (*Liverpool Medico-Chirurgical Journal*, February, 1900), must be looked upon as unique. The patient was an only

child, and her parents were dead, of influenza and pulmonary tuberculosis respectively. She had had an attack of measles and one of chickenpox. Six months prior to death the child began to suffer from palpitation of the heart and became nervous, and at the same time protrusion of the eyeballs was first noticed. She was large and well formed for her age, but behaved in an infantile manner, crying hysterically for hours after her friends had left. Menstruation had not yet appeared. Exophthalmos was marked. The thyroid gland was slightly but perceptibly enlarged. There was no thrill, but a systolic bruit was heard on auscultation over the goitre. The action of the heart was rapid, 132 in the minute, and regular, and the sounds were clear. There were pretty general tremors. The temperature was normal, with a single slight exception. The treatment consisted of rest in bed, and tincture of belladonna ♏ iii., potassium bromide gr. x., thrice daily. Nausea and vomiting set in, a little blood and some coffee-ground material being evacuated on several occasions. The condition of the patient grew gradually worse, and death resulted from exhaustion. Most unfortunately, an autopsy could not be secured. Of course, it is difficult to say in this case to what causes death is to be attributed, and to determine what part if any the exophthalmic goitre played in bringing about the fatal issue. The opinion is expressed that gastric ulceration did not exist, but the grounds for this exclusion are not entirely obvious.

INTERNATIONAL MEDICAL PRESS CONGRESS IN PARIS.

One of the most distinctive features of the International Medical Congress just ended in Paris was the meeting of medical journalists from all parts of the world. This reunion of medical scribes may on the whole be regarded as a success. Neither the United States nor Great Britain was conspicuous so far as numbers were concerned, but the papers read by Dr. Fassett, editor of the *American Medical Journalist*, and by Dr. Squire Sprigge, of *The Lancet*, were excellent in quality. Dr. Fassett gave a sketch of the origin and rise of American medical journalism, stating that the first paper devoted to medical matters was founded in this country at the end of the last century, and that at the present time there were two hundred and seventy-eight medical journals in the United States, a sufficiently convincing proof of enterprise. Dr. Fassett insisted that medical journals should avoid sensational news and the discussion of vague theories, and should also be written so as to be intelligible to general practitioners who are not specialists. The paper read by Dr. Sprigge was exceptionally interesting, and was recognized as perhaps the most suggestive submitted to the congress. In it was given a history of the early struggles of *The Lancet* and of the successful attempts of its editor to combat the nepotism prevalent at the hospitals and at the medical schools in those days. The financial situation of *The Lancet* and *British Medical Journal* was described, showing that the prosperous condition of these papers rendered them entirely independent and able to supply freely the means to make original researches and investigations, to depute experienced technicians to follow armies on the field, to study epidemics in all parts of the world, and to analyze all sorts of food-stuffs. The results of these investigations had been most beneficial in their effect on the laws of the country with regard to medical education, public health, adulteration of food, etc.

A paper was read by Dr. Alban on the right of reproduction of scientific illustrations. This paper provoked much discussion, but no definite conclusion on the matter was reached. A committee, however, was elected to discuss the question with publishers, medical men, and legislators, and to study generally the question of literary property from a medical point of view. It would appear that the work of the International Medical Press Congress should be productive of much good in the future.

PLEA FOR A MEDICAL DEFENCE UNION IN THE UNITED STATES.

The medical profession has many difficulties with which to contend, and one that undoubtedly weighs heavily upon its members is the disadvantages under which they labor in defending malpractice suits. An action of this description brought against a physician does not only affect him personally, but upon his victory or defeat depend to a certain extent the good name and financial position of his medical brethren at large. This being so, it is reasonable to expect that every effort will be put forth by the accused to win his suit, as he is as a matter of fact fighting in the interests of the entire medical profession. But unfortunately it often happens that the money necessary to employ the best measures to insure success is lacking, and that consequently irreparable injury is done to physicians throughout the country.

Dr. Donald B. Pritchard, writing in the *St. Paul Medical Journal*, July, proposes that a medical defence union, formed on the lines of that now in existence in England, should be established in this country. His idea is to organize a mutual association, the membership of which should be confined to those who belong to the State or some properly organized medical society. In order that the organization might be of the highest standing, it would not be proper to defend one guilty of gross malpractice. That this might be accomplished, every case should be submitted to a standing committee, who after a thorough examination would decide whether or not it would be proper for the association to defend. If the decision is not satisfactory to the member, then a board of arbitration should decide the matter. When the association undertakes the defence, the member involved should be pledged to be absolutely guided by it in the conduct of the case, and that it should not pay any part of the verdict, simply incurring liability for all expenses of the trial. Dr. Pritchard says that he has communicated with a number of well-known lawyers, and that they all say that there is no legal bar to such an association, and that there is no more likelihood of juries

being adversely influenced than in the case of any other corporation. The suggestion is at least worthy of consideration, and the good work done by the English Medical Defence Union should act as encouragement for the establishment of a similar organization in this country.

News of the Week.

A Roosevelt Hospital Ambulance was run into on Sunday evening by an Eighth Avenue car and overturned. The driver and a policeman riding on the ambulance were severely injured, the surgeon received a scalp wound, but the patient, who had shortly before fallen from a third-story window, received no further injury. Another ambulance was called and gathered up the entire party and took them to the hospital.

The Zeta Phi of Syracuse University.—During the past year the women of Syracuse University College of Medicine, have organized Zeta Phi (letters which might appropriately stand for "Zeuxis philōn"), the first and only women's medical fraternity in this country. Dr. Elizabeth Blackwell has consented to become a charter member, she having been graduated from this college and the first woman to receive the degree of M.D. in America. The purpose of the fraternity is to bring the women of the medical profession into closer touch with one another.

Dr. John B. Murphy has accepted a professorship in surgery and clinical surgery in the Northwestern University Medical School (Chicago Medical College). Dr. Murphy has also been appointed surgeon-in-chief of Mercy Hospital with the direction of the surgical teaching in that hospital. He will give two clinics each week at the hospital. The hospital now contains two hundred and sixty beds, with abundance of clinical material. A new amphitheatre with a seating capacity of three hundred is in progress of construction.

The American Electro-Therapeutic Association.—The tenth annual meeting of this association will be held in this city in the hall of the Academy of Medicine on September 25th, 26th, and 27th. The headquarters of the association will be at the Hotel Bristol, Forty-second Street and Fifth Avenue. There is a programme of sixty-two titles, many of them containing the promise of great interest. In addition to the reading and discussion of papers, visits are planned to the Electric Vehicle Transportation Company's barns, the central station of the New York Telephone Company, the power house of the Metropolitan road, Ninety-sixth Street and First Avenue, the cable machinery of the Brooklyn Bridge, Columbia College library and laboratories, and St. Luke's Hospital. The ladies' auxiliary committee have planned excursions to visit the Stock Exchange, Trinity Church, and the Aquarium; Central Park East, the Obelisk, and the Metropolitan Museum of Art; Central Park West and the Museum of Natural History; and Columbia College, St. Luke's Hospital, Morningside Park, and Riverside Drive. The officers of the association are: *President*, Dr. Walter H. White, of Boston; *Vice-Presidents*, Drs. D. Percy Hickling, of Washington, and Charles O. Files, of Portland, Me.; *Secretary*, Dr. George E. Bill, of Harrisburg, Pa.; *Treasurer*, Dr. R. J. Nunn, of Savannah. The chairman of the committee of arrangements is Dr. Robert Newman, 148 West Seventy-third Street, New York City. All members of the medical profession are invited to attend the meetings.

Nurses in the Spanish War.—A society to be called the Spanish-American War Nurses' Association was organized in this city last week at a reunion of some sixty army nurses who had served in the Spanish war. The meeting was held at the New York Hospital. The constitution adopted makes only those who were in actual service not less than one month during the Spanish war eligible to membership. Of these there are at least five hundred. The following officers were elected: *President*, Dr. Anita Newcomb McGee, acting assistant surgeon United States army, Washington; *Vice-Presidents*, Dr. L. A. Hughes, Boston; Miss Hibbard, Manchester, N. H.; Dr. Isabel Cowan, Presidio Reservation, California; Miss Hobson, New York; Miss McCloud, now serving in the Philippines; Miss Walton, New York; Miss Miselback, now serving in Santiago, Cuba; Miss Robbins, Miss Dreyer, now in the Philippines; Miss Read, Baltimore; *Recording Secretary*, Miss Lela Wilson, Boston; *Corresponding Secretary* and *Treasurer*, Mrs. George Lounsbury, Charleston, S. C. The association will meet in Washington next year.

Sickness and Destitution in Alaska.—According to a report recently submitted by the captain of the revenue cutter *Bear* to the chief of the revenue cutter service in Washington, a most deplorable condition of affairs exists among the natives on the Alaska coast north of Nome and also on the Siberia coast. The *Bear* sailed along the north coast of Siberia as far west as Kolutchin Bay. When off Sinrock an officer and a surgeon were sent ashore and reported an epidemic of measles and pneumonia, with many of the natives sick. Medicines were left and the vessel proceeded to Port Clarence. Here there was found to be much sickness, and many deaths had occurred among the natives. The surgeon prescribed and medicines were left. The same conditions prevailed at Cape York, Whalen, King's Island, and all the other places touched at in Siberia. At St. Lawrence Bay there had been thirty-six deaths out of a total population of two hundred and ninety-three. This unusual prevalence of epidemic disease has thoroughly demoralized the natives. Instead of busying themselves in laying in the winter's supply of food, as they are always obliged to do at that time, they remained in their huts consuming what little food was left them. The *Bear* has returned to that coast carrying a large quantity of supplies for the destitute natives. At Teller, Alaska, the Esquimaux are suffering greatly from influenza, fully one-half of those near the station having died. In some cases whole families have dis-

appeared, both parents and children being dead. In others the parents and some of the children have died, leaving young children orphans with no near relatives to feed or care for them. The salmon are running in their waters, but there are not sufficient numbers of well people to catch them, and thus provide for the present and for next winter. The ravages of the disease have been so great that a panic has seized the native population, and the dead are left unburied in their homes. It is said that the records for the last half-century show no such distress among the natives as that which is now prevalent along the whole Bering Sea coast.

The Heat Mortality in New York City.—One hundred and fifty-two deaths were caused in this city last July by sunstroke, according to the bulletin of the State board of health. The State is now free from smallpox for the first time in some months. There were eight hundred and fifty-six deaths from accident and sunstroke in the State in July, five occurring from lightning strokes.

A New Dispensary Building.—Plans have been submitted to the department of buildings for a six-story and basement dispensary building to be erected by St. Bartholomew's Episcopal Church at an estimated cost of $200,000 on East Forty-second Street, adjoining the mission house built by the church. The first story of the building will be of Indiana limestone and the superstructure of brick.

Dr. Smith Ely Jelliffe assumed editorial control of the *Medical News* on September 1st, succeeding Dr. J. Riddle Goffe, who has so ably conducted the journal ever since its transfer from Philadelphia to this city. Dr. Jelliffe has been for some time on the editorial staff of the *News*, and may be trusted to maintain the high standard established by Dr. Goffe.

Women in the British Association.—Previous to the opening of the annual meeting of the British Association for the Advancement of Science at Bradford on September 5th, the general committee debated the motion of Professor Hartop that women should be admitted to membership in the association. Sir Henry Roscoe, vice-chancellor of the University of London, and others supported the proposition, but Sir John Evans, former president of the association, counselled caution. It was decided finally to admit women, making membership of the general association a precedent to election to membership in the sections.

Yellow Fever in Havana.—Although the general health of Havana, thanks to American sanitary methods, is better than ever before, yellow fever has prevailed quite extensively this summer, fifty deaths from this cause having been reported in August. This is, according to the consensus of testimony, due almost entirely to the large immigration of non-immunes. Seventy-five per cent. of the total number of cases were among immigrants from Spain who had been in Havana less than a year. Since July, 1899, twenty-six thousand immigrants have arrived in Havana and ten thousand are expected during the next two months. Many of these come to Havana on the mere chance of finding work. They accept the first employment that offers, often taking very small pay, instead of going to the country districts, where more men are needed and the rate of wages is better. Many of them remain in unhealthful conditions, and as nearly all are non-immunes, yellow fever increases. Governor-General Wood has recently appointed a board of immigration consisting of Drs. Gorgas and Havard and two Cuban physicians, and they will draw up regulations concerning immigrants. Cheap but healthful barracks will be built on the other side of the harbor, where the immigrants may have free lodgings. A small sum will be charged them for board. The board of immigration will interest itself in obtaining employment for the immigrants, placing as many of them as possible in the provinces.

The Plague in Glasgow, which was thought at the end of last week to have been checked, has broken out afresh. Up to Thursday last the total number of cases was sixteen, and one hundred and fourteen suspects were under surveillance. There has been a recrudescence of the disease in India, over one thousand deaths from plague having occurred there last week.

The Cholera in India.—A telegram received in London from the Viceroy of India states that the deaths from cholera for the week ending September 1st were 1,930 in the native states and 4,021 in the British districts.

Electric Ambulances.—Roosevelt Hospital will soon have two electric ambulances which have been given to the institution, one of them by a physician. The ambulances, which will have a maximum speed of sixteen miles an hour, are seven and one-half feet long, and can carry three patients at one time. The only other electric ambulance in the city is one belonging to St. Vincent's Hospital, but two others are now under construction—one for the New York and one for the Presbyterian Hospital.

The Horror at Galveston.—In the frightful storm which visited Galveston and other Gulf towns last Saturday, the large buildings—asylums, hospitals, and school-houses, which had been sought out as places of refuge suffered more than frailer buildings. An orphan asylum, containing many children and numbers of refugees, collapsed, as an eye-witness expressed it, "like a house of cards," and most of the inmates perished. St. Mary's Infirmary was completely demolished, and all the sisters and ninety patients and other inmates were drowned. The Catholic orphan asylum is also reported to have been destroyed, all the children and sisters being drowned. A home for aged women fell, and a school-house near it was also destroyed, burying in the ruins numbers of persons who had taken refuge there. Two physicians were killed while on the way to see their patients. One was drowned, the other struck by a falling beam or other heavy object.

The New Brunswick and the Maritime Medical Associations.—The twentieth annual meeting of the New Brunswick Medical Society was held at St. John,

N. B., on Tuesday, July 17, 1900. The meeting was called to order by the vice-president, Dr. R. L. Botsford, of Moncton, N. B., who explained that the society had been called together to transact business, after which the sessions would merge into those of the tenth annual meeting of the Maritime Medical Association. The meeting of this association was held on July 18th and 19th. The election of officers of the New Brunswick Medical Society resulted as follows: *President*, Dr. G. T. Smith, of Moncton; *Vice-President*, Dr. S. C. Murray, of Albert; *Treasurer*, Dr. C. G. Melvin, of St. John; *Corresponding Secretary*, Dr. J. H. Scammell, of St. John; *Recording Secretary*, Dr. W. Leonard Ellis, of St. John; *Trustees*, Drs. J. C. Mott, Murray, and Bridges. The next annual meeting will be held at Moncton. The election of officers of the Maritime Medical Association resulted as follows: *President*, Dr. W. S. Muir, of Truro; *Vice-Presidents*, for Nova Scotia, Dr. T. Trenaman, of Halifax; for New Brunswick, Dr. P. R. Inches, of St. John; for Prince Edward Island, Dr. A. Ross, of Alberton; *Treasurer*, Dr. T. D. Walker, of St. John; *Secretary*, Dr. G. M. Campbell, of Halifax.

The Study of Psychology.—One of the subjects discussed at the International Congress of Psychology held in Paris during the present summer was the establishment of a permanent institute for psychical research. The board appointed to deal with the matter contains MM. Ribot, Richet, Janet, Félix Alcan, d'Arsonval, Bouchard, Duclaux, Marey, Fouillée, Bergson, Sarde, and Séailles, for France; Sir William Crookes, Frederic Myers, Prof. James Sully, Prof. Oliver Lodge, and Oswald Murray, for England; and Profs. William James, of Harvard, and Mark Baldwin, of Princeton, for the United States.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 8, 1900. August 31st.—Assistant Surgeon E. V. Armstrong granted sick leave for one month. September 1st.—Passed Assistant Surgeon C. M. De Valin ordered to additional duty at the navy yard, Portsmouth, N. H. September 3d.—(Orders issued by commander-in-chief of Asiatic station.) Assistant Surgeon A. G. Grunwell detached from the *Monocacy* and ordered to the *Brooklyn*. September 4th.—Assistant Surgeon T. M. Lippitt detached from the *Newark* and ordered to the *Monocacy*. September 6th.—Surgeon A. C. H. Russell detached from the naval hospital, Yokohama, Japan, and ordered to proceed home and to wait orders.

Obituary Notes.—Dr. Samuel F. Gilbert, of Elysburg, Northumberland County, Pa., died August 30, 1900, aged fifty-five years. He was a graduate of the University of Pennsylvania, receiving his diploma in 1872. He located first at Sunbury, then at Augusta, from which place he removed to Elysburg about twenty-five years ago. Dr. Gilbert was born August 7, 1845, near Halifax, Pa.

Dr. Joseph Washington Clowes, one of the oldest and best-known dentists of New York, and the last surviving member of the first class graduated at the Baltimore College of Dental Surgery, died at his home in this city on September 9th, at the age of seventy-nine years. He began the study of dentistry in 1838 in the office of Dr. J. Smith Dodge. The following year he entered the Baltimore College of Dental Surgery. In 1842 he opened an office in New London, Conn., and came to New York in 1850, remaining in practice here until about a year ago, when he retired on account of ill health.

Dr. Dennis Dowling Mulcahey died on September 11th, at his home in Newark, N. J., after an illness of a few days. He was born in Tipperary, Ireland, in 1848, and began the study of medicine before coming to this country, but took his degree from the College of Physicians and Surgeons in this city in 1872. During the Fenian uprising of March 7, 1867, he went from Killmaltock to the aid of the wounded at Limerick Junction, and was picked up by the constabulary and imprisoned for a year and a half. Upon his release he came to this country and found a friend in Dr. William O'Gorman, of Newark, in whose office he completed his studies. He was known as one of the best Irish historians in this country, and possessed a very valuable library of books on Irish history and kindred subjects. He was himself a vigorous writer and his pen was always at the service of his native island.

Obituary.

JACOB M. DaCOSTA, M.D., LL.D.,

PHILADELPHIA.

Dr. Jacob M. DaCosta died suddenly on Tuesday evening, September 11th, at his country home in Villanova near Philadelphia. He had but recently returned from York Harbor, Me., where he had been passing the summer, and was apparently in excellent health. Cardiac disease was the cause of his death. Dr. DaCosta was born on the island of St. Thomas, West Indies, February 7, 1833. He received his literary and classical education in Germany and pursued his medical studies at the Jefferson Medical College in Philadelphia, from which he was graduated in 1852. The following two years he spent in study in the hospitals and schools of Paris and Vienna, and in 1854 returned to Philadelphia and established himself in practice. He soon made for himself a reputation as a diagnostician of more than ordinary acumen, and though always regarding himself as a general practitioner he was by preference drawn to a special study of diseases of the thoracic organs. His contributions to medical literature have been large and upon a variety of subjects, but he was perhaps best known as the author of a classical work on "Medical Diagnosis," the first edition of which appeared in April, 1864, and the ninth and last only a few weeks ago.

In 1864 Dr. DaCosta was appointed lecturer on clinical medicine at Jefferson Medical College, in 1872 was elected to the chair of the theory and practice of medicine in the same institution, and a few years ago was retired at his own request, being made emeritus professor of the practice of medicine and of clinical medicine. He was at different times attending physician to the Episcopal, the Pennsylvania, and the Philadelphia hospitals. He was a fellow of the College of Physicians of Philadelphia, and for several years its president.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 6, 1900.

Notes on the Treatment of Ataxic Patients by Co-ordination Exercises, with Demonstration of Two Patients.—James J. Putnam says that in the treatment by this method several points should be strictly borne in mind: (1) It is skill, not strength that it is sought to develop. (2) It is necessary to begin with relatively elementary motions, such as drawing the leg up and down in bed, or moving the finger from one spot to another. The patient should be called upon to perform them with promptness and accuracy and at the word of command. (3) Dulness, monotony, and fatigue, on the one hand, and superficiality on the other, are the rocks to be avoided, both by the introduction of sufficient variety into the exercises, and by giving them something of the entertainment of games of skill. (4) It is not well to let the patient get on without an instructor, using a prescribed set of exercises. The necessity for obedience to the word of command, which calls for close attention and for movements which come to have something of the character of involuntary reflexes, is a great help in stimulating both the conscious and the sub-conscious attention and the power of instinctive control. (5) Weak, anæmic patients, and those suffering constantly from pains and crises, those with atrophy, rupture of tendons, cardiopathy, aneurism, obesity, arthritis, laxity of ligaments, or severe arthropathy are not good subjects for the treatment.

Notes on Dermatitis Venenata.—George F. Harding says that this term is used to indicate forms of inflammation or irritation of the skin produced by the action of substances applied externally. The number of these substances is very large, including familiar garden plants and wild flowers, drugs applied to the skin therapeutically, substances used in trade, or found in articles of clothing, household articles, etc. There are also animal irritants. The form of dermatitis produced is, as a rule, of the erythematous or eczematous type, but occasionally deeper grades of inflammation are seen. Itching, burning, and pricking are usual, and sometimes there is numbness. The author takes up a number of irritating substances and discusses them in detail, also reporting a number of cases.

Two Cases of Abnormal Sexual Development.—George G. Sears describes the case of a boy in whom there was imperfect development of the genital organs, accompanied by dwarfism and feminism; and the case of a girl in whom the failure of the genitals to develop was associated with a tendency to gigantism and the assumption of male characteristics. The thyroid gland was not felt in either case.

The Scope and Aim of the Section's Work.—By Col. Kenneth Macleod, president of the Section of Tropical Diseases of the British Medical Association.

New York Medical Journal, September 8, 1900.

Feeding the Infants of the Poor with Unsterilized Cow's Milk.—G. T. Palmer enumerates the objections to sterilization, and states that in one of the Chicago institutions the following method was adopted: A certified milk was obtained and the method of dilution and of addition of cream and milk and sugar carried out as laid down in numerous text-books. Palmer began with rather a larger percentage of proteids and decreased as the age of the child increased. The milk thus prepared was packed in sterile jars and placed in large buckets of ice, in which way it is carried home by the mother. If placed in a cellar or in some way protected from heat, this ice will preserve the food the greater part of the day. Each morning the infant is brought to the kitchen for inspection and the weight and character of the stools are regularly noted. At the same time the nursing bottles and nipples are inspected and the parents are repeatedly warned and advised regarding the proper method of feeding. Aside from this, it is customary to have the superintendent and nurses call at the homes of the patients to see that directions are carried out. During the summer about seven hundred applications for food and medical care have been made, invariably for babies more or less ill; for so long as the infant is comparatively well these people see no necessity of asking assistance. The total mortality has been three.

The First-Aid Packet in Civil Practice and the Organization of First-Aid Societies.—M. J. Shields gives his experience in organizing a society of the kind named among the mining population of one of the Pennsylvania districts. He makes a plea for the extension of this work in localities where men are, from their occupation, particularly liable to accidents.

A Plea for the Early Naked-Eye Diagnosis and Removal of the Entire Organ, with the Neighboring Areas of Possible Lymphatic Infection, in Cancer of the Larynx.—By J. N. Mackenzie.

Report of a Case of Nephrectomy for Ascending Tuberculosis, with Some Remarks on Cystoscopy and Catheterization of the Ureters in Women.—By H. N. Vineberg.

Severe Operations on the Throat and Nose; Report of Five Cases.—By A. A. Bliss.

The Surgical Treatment of Laryngeal Cancer.—By J. Solis-Cohen.

Philadelphia Medical Journal, September 8, 1900.

Rheumatic Fever.—J. Newton Hunsberger believes that the multiplicity of cases at times encountered is due entirely to atmospheric conditions. He has observed most cases in autumn. Heredity plays a distinct rôle. It was shown in seventy-five per cent. of cases. A case is given showing the effect of an overproduction of urates, and another to illustrate the effect of a lessened excretion. In treatment four indications must be met: (1) To prevent fresh chilling of parts; (2) to keep them at rest; (3) to modify the condition of the blood and neutralize the poison; (4) to prevent, if possible, inflammation of the endocardium and pericardium. Rules of treatment are laid down, and as much more than a gallon of water a day as the patient can be made to take is advised. Water meets most of the indications. He regards salicylic acid and its various combinations to be absolutely contraindicated.

Prostatic Calculus.—John C. Spencer says a distinction should be drawn between essential and adventitious or exotic calculus of the prostate. The latter may enlarge by accretion of urinary salts, and invade the gland parenchyma, protruding into the prostatic urethra to a small extent. The paper treats chiefly of the essential form. The origin is to be found in the protoplasm of degenerated gland epithelia about which colloid material is deposited. The symptoms become manifest only when the calculus may have eroded through into the urinary passages, or by its size either paralyzes the vesical sphincter, causing incontinence, or produces vesical irritation and tenesmus, or is an obstruction to the outflow of urine. The latter was the case in an instance recorded by the writer.

Legal and Judicial Disagreement and the Shortcomings of Medical Witnesses.—By Irving C. Rosse.

Note on the Frequency of Renal Casts without Albuminuria.—By C. F. Martin and F. B. Jones.

Heroin in the Treatment of Phthisical Cough and Whooping-Cough.—By M. Loewenthal.

A New Forceps for Holding Slides in Staining.—By Thomas S. Kirkbride, Jr.

The Etiology and Pathology of Empyema.—By Joseph McFarland.

Medical News, September 8, 1900.

Trophic Changes in Consumption: a Contribution to the Symptomatology of this Disease.—Henry Herbert considers scrofulosis as having a certain analogy to syphilis in that it constitutes the primary and secondary stages of tuberculosis, and reappears as tuberculosis of the lungs or of other organs like the tertiary lesions of syphilis. He is not a believer in the hereditary theory of consumption, but fully agrees with the most radical views regarding the infectiousness of the disease. The writer illustrates by the relation of cases the curious coincidence of the side on which the trophic signs occur and that in which the lung is diseased. His researches show the possibility of recognizing the early and latent stages of consumption sooner than with the present means or methods, and of ascertaining the side affected, if physical examination does not give satisfactory evidence. The side primarily affected is indicated by the occurrence of trophic disturbances on that side.

The Effect of Flashes of Electric Light on the Eye.—Dunbar Roy believes there have been more cases observed than reported of temporary injury to the eye through intense electric flashes. The danger of the electric light is illustrated by a series of examples from practice. In a number of instances cessation from school work has had to be ordered because of the injurious incandescent lights; and in other cases student's lamps had to be substituted. Electric ophthalmia is discussed. It seems probable that domestic lights are injurious to the eye in proportion to the amount of ultra-violet rays they contain. The Welsbach gas light seems less injurious as a light by which to read and work than others. There should always be an under shade to mitigate the light.

The Physiology of Sleep.—H. H. Stoner goes over the various theories which have been advanced from time to time to account for the phenomena of sleep. Recent discoveries in anatomical construction and the physiological action of the nervous system give a clearer insight into the manner in which sleep is produced. Neurons and their relations and functions are entered into. Sleep is, according to the theory advanced, not the result of an outside

influence exerted upon the brain as a whole, but is due to metabolic changes which take place in the body of the nerve cell as the result of normal fatigue.

The Status of General Anæsthesia in 1900.—By M. L. Maduro.

Graves' Thyroid Disease.—By O. T. Osborne.

Journal of the American Medical Ass'n, Sept. 8, 1900.

Traumatic Insanity.—E. G. Carpenter reports a case and calls attention to injury of the cranium as one of the rare causes of insanity. An injury producing irritation of membranes to the degree of causing spasms, contractures, and paralysis could also disturb cell elements of the cortex so as to induce insanity. He concludes that conditions already present may predispose to the causing of insanity by an injury. The insanity should speedily follow the injury. The extent of the concussion may be a determining factor. The locality on the cranium may be an important consideration.

Exophthalmic Goitre.—F. W. Higgins discusses symptoms, theories of pathology, the toxæmic theory, functions of the thyroid, myxœdema, and indications for treatment. There is probably a fright centre as well as a speech centre, and this may be congenitally weakened. A physical manifestation in the thyroid in a predisposed person may assume a permanent character from an inherent predisposition. Thus the thyroid is still recognized as a prime factor, but only as one of a chain, and treatment is directed to the breaking of the chain at its most vulnerable point.

Typhlitis, Perityphlitis, and Appendicitis in Infancy and Childhood.—J. H. Byrne discusses first the causation and relative frequency and reviews the teachings of the past as they indicate the original seat of inflammation. The anatomy, etiology, and predisposing causes are studied, and a case is given in which hardened fecal masses were expressed by digital manipulation with very satisfactory results.

Pseudo, Modified, or True Smallpox—Which is it?—By H. M. Bracken.

Measurement of Chicago School Children.—By W. S. Christopher.

Serum-therapy in Croupous Pneumonia.—By J. C. Wilson.

Pseudo (?) or Modified (?) Smallpox.—By T. J. Happel.

British Medical Journal, September 1, 1900.

A Discussion of the Enlargements of the Spleen in Children.—Samuel West calls attention to the course and duration of splenic enlargement of infants and its relation to rickets and syphilis. He finds an enlarged spleen in fifty per cent. of all cases of congenital syphilis and still more frequently in still-born syphilitic fœtuses. Enlargement is not constant in rickets, and there is no relation between the size of the viscus and the degree of the rickets. Neither the syphilis nor the rickets is the sole cause, and probably not the cause at all except perhaps indirectly by means of the ill health to which either leads. As to the relation which exists between the splenic enlargement and the profound anæmia so often associated with it, three alternatives present themselves: the enlargement may cause the anæmia, may be caused by it, or both may result from some common cause.

Congenital Hypertrophic Stenosis of the Pylorus.—J. H. Nicoll finds records of some thirty undoubted cases. His own case was that of a baby aged six weeks, who from the second week after birth vomited the stomach contents fifteen or twenty minutes after each meal. Vomiting was not preceded or accompanied by hiccough, nausea, pain, or difficulty. Between attacks the child seemed to be perfectly comfortable until hunger induced another meal, when the same results would happen. Emaciation naturally followed. A Loreta's operation was done with perfect success. The child was living and healthy a year after.

An Explanation of the Cause of Infantile Scurvy, with Suggestions as to its Prevention.—C. E. Corlette advances the theory that the sterilization and to a less extent the pasteurization of milk deprive it of its normal citric-acid contents, and that it is this deficiency which is the cause of scurvy symptoms. He advises along with milk the addition of lime-juice or a citrate, and gives his formula for this procedure. The article is well worthy of perusal by all interested in the matter of infant feeding.

Ambidexterity: a Plea for its General Adoption.—E. Noble Smith traverses familiar ground, calling attention to the possible influence of one-sided use of the body in the production of deformities.

Münchener medicinische Wochenschrift, August 21, 1900.

Pneumonia following Laparotomies in the Neighborhood of the Diaphragm.—In the opinion of George Kelling this is the most serious of the complications attending operations of this sort, especially those performed on the gastro-intestinal canal. From its causation it may be divided into: (1) Aspiration pneumonia, due to inhalation of vomitus, and which is particularly infectious in cases of œsophageal or gastric carcinoma when breaking down has taken place; (2) pneumonia due to pulmonary infarcts resulting from emboli originating from the vessels ligated; (3) hypostatic pneumonia, observed in the aged and secondary to imperfect aeration of the lungs and impaired heart action; (4) pneumonia occuring during epidemics. In addition to these there is a set of cases which give the impression that the infection was conveyed at the time of operation, and as other factors can usually be excluded the author believes that this often takes place through the contact of the air with the interior of the abdominal cavity. To guard against this danger the operating-room must be kept as dust-free as possible, with which object frequent wiping with moist cloths, filtration of the air admitted for purposes of ventilation, and flooding of the floor with water are recommended.

Infection through the Conjunctival Sac.—Mayer performed a large number of experiments on animals, demonstrating the possibility of bacterial invasion of the circulation and generalized infection through the medium of the conjunctiva. This takes place with great rapidity after inoculation with anthrax, pest, chicken cholera, mouse typhus, in small animals with glanders and psittacosis (Nocard). Pseudo-tuberculosis gives a subacute course; in larger animals psittacosis, glanders, and tuberculosis are very chronic. Tetanus and diphtheria are fatal through the formation of toxins; diphtheria and the staphylococcus pyogenes aureus produced local infections, while the organisms of cholera, typhoid, and actinomycosis were not able to invade the system, the tears appearing to have a special inhibiting effect on cultures of the former two, while on the contrary the growth of the diphtheria bacillus was encouraged.

The Occurrence of Rhodan in the Nasal and Conjunctival Secretion.—O. Muck tested the nasal secretion for this constituent of saliva by introducing cotton tampons moistened with diluted ferric-chloride solution acidulated with hydrochloric acid. A reddish or yellowish brown was produced where the nasal secretion came in contact with the reagents. As a corroborative reaction chemically clean filter paper was saturated with a mixture of concentrated hydriodic acid, dilute sulphuric acid, and starch solution, and dried. When this is applied to the nasal secretion a blue spot is produced, showing that iodine has been set free, owing to the reducing properties of the rhodan base.

Sugar as an Oxytocic.—Max Madlener has had good results with sugar solution in cases of insufficient labor pains. He gives one ounce of sugar dissolved in eight ounces of water, repeating if necessary. If more acceptable to the palate the draught may be flavored with tea or rum. Nausea is never produced. In from one-half to one hour after administration the effect is manifest, the uterine contractions being greatly stimulated, while the physical pain is somewhat diminished.

My "Position Treatment" in Abnormalities of Form, Position, and Size of the Uterus.—By Beckers.

The Alexander-Adams Operation in Retroflexio Uteri Mobilis.—By Carl Peters.

Deutsche medicinische Wochenschrift, August 23, 1900.

Is Alcohol a Food or a Poison?—Kassowitz maintains that it is not so much a question as to whether alcohol *per se* is toxic or nutritive, for it can hardly be denied that it is an active poison capable of causing the death of any animal or vegetable protoplasm with which it comes in contact, but rather as to whether in spite of these injurious properties it can still be of value to the organism and serve to sustain it. A food-stuff to be classed as such must not only be capable of supplying the organism with energy to be dissipated as heat and in the performance of work, but must also under proper conditions enter into the bodily structure and replace tissue that has become worn out. Recent investigation has shown clearly enough that alcohol is easily and abundantly oxidizable in the human body, but the mere proof that a substance is consumed in this way does not entitle it to rank as a food, and still less can this supposition be entertained if in addition it at the same time causes decomposition and destruction of living protoplasm. That alcohol does this is not to be doubted in view of the present knowledge of metabolic processes, and this granted, it is evident that a substance capable of destroying body tissue cannot also at the same time serve to build it up and replace damaged parts. Therefore the position that alcohol may play the double rôle of food and poison is untenable, and the sooner it is dropped from the list of drugs for internal administration the better it will be for physician and patient.

What is the Rôle of the Tube in the Therapeutic Application of the Roentgen Rays?—Sträter divides the tubes used therapeutically into hard and soft, with intermediate degrees, basing the gradations on the degree of penetration into the tissues exhibited. Soft tubes are those whose rays manifest their activity principally in the skin and muscle, while those that penetrate the overlying structures and are only partially blocked even by the bone are designated as hard. These differences may be estimated by the use of the fluorescent screen, on which the intensity of the rays is commensurate with the degree of illumination and the hardness proportionate to the sharpness of contrast between the illuminated object, *e.g.*, the hand, and the surrounding field; thus the harder the tube the less plainly will the soft parts show and the less intense will be the shadow of the bones. Therapeutically soft tubes are to be used when it is intended to confine the remedial action to the upper layers; hard ones when deeper structures are to be influenced.

A Fatal Case of Septicæmia Beginning as Angina Follicularis.—The case described by Noltenius began apparently as a simple tonsillitis confined to the left side. At the same time there was a slight redness of the skin on the opposite side, which gradually increased in extent and the skin became somewhat swollen and painful. The local symptoms in the throat became more severe and simulated a diphtheritic infection, so that antitoxin was injected. The treatment was not effective, and the patient had a daily afternoon temperature of 102.5° F. with morning remissions. On the eighth day the left calf and both forearms became intensely painful and gave evidence of a well-marked lymphangitis, and the temperature went up to 103.5° F., continuing high until the patient's death four days later from cardiac weakness. The case is interesting as affording proof of the possibility of a general infection taking place through the medium of the tonsils.

The Treatment of Aneurisms by Electrolysis through the Introduction of Wire.—By A. Bernheim.

The Doubtful Value of Antitussin as a Remedy in Whooping-Cough.—By P. Krause.

Fifth Report of the Malarial Expedition.—By R. Koch.

Berliner klinische Wochenschrift, August 20, 1900.

Therapeutic Trials with Alternating Currents of High Frequency and Tension (Tesla Currents).—Toby Cohn describes a series of experiments made by himself alone, which were similar to those made by himself and Loewy. He arrived at practically the same conclusions. He could not make out any change in blood pressure or in tissue change. There were some subjective sensations which made the patients say they felt better, especially in regard to ability to sleep well. Cohn thinks that the current may have a suggestive influence, and that to this are due all the reported benefits.

The Effect of Tesla Currents on Metabolism.—A. Loewy and Toby Cohn made a series of experiments on persons subjected to the influence of the Tesla currents by inclosure within large solenoids, and by the estimation of oxygen absorbed and carbonic acid gas given off. They were unable to determine that the conditions of the experiments produced any effect whatever.

A Contribution to the Critical Examination of Milk Preparations.—By W. Caspari.

Contributions to the Derivation of Sugar from Albumin.—By J. Wohlgemuth.

French Journals.

The Parasitic Origin of Eczema.—L. Brocq concludes a clinical lecture: (*a*) In the present state of our knowledge the existence of a specific microbe pathogenic of eczema remains still to be demonstrated. The microbe may exist, but it has not been proven. (*b*) Pure primary lesions (closed vesicles) of true vesicular eczema do not contain any microbe discoverable by procedures now known in bacteriology. (*c*) The various microbes (and in particular the staphylococcus) which exist in abundance upon the oozing or crusted surfaces of eczema constitute secondary infections, whose direct effect upon pure eczema begins to be suspected, but their presence does not explain its nature. These microbes are the cause of most of the complications and of the polymorphous eruptions which so often change the typical evolution of pure eczema.—*Journal des Praticiens*, August 25, 1900.

Entero-Colitis.—P. Froussard, in a clinical study of mucomembranous entero-colitis concludes with a consideration of the dermatoses in its course. A certain number of cutaneous manifestations of the polymorphous erythema type appear, especially after paroxysmal crises, which are accompanied by infectious phenomena, and which ought to be attributed to the latter. There are other dermatoses of remittent or chronic course: urticaria, prurigo, pruritus, eczema, and seborrhœa, which pursue an equal course with the entero-colitis. Especial attention is directed to a miliary pustular recurrent eruption of the face, especially seen in women who suffer from gastro-intestinal troubles as well as from nervous antecedents.—*La Presse Médicale*, August 29, 1900.

The Pathogeny of Pellagra.—Professor Babès says pellagra is on the increase in Roumania. He gives a *résumé* of histological researches in collaboration with Sion, which point to the action of a toxic substance in pellagra. This substance, formed in the blood, has the property of suppressing the toxic action of the extract of altered maize. This substance can be found in the blood serum of subjects of pellagra who have been cured or improved. It possesses the specific features of action upon the toxic extracts of spoiled maize coming from pellagra-infected regions, while other serums experimented with do not have this action.—*La Médecine Moderne*, August 22, 1900.

Organization of the Fight against the Plague in Russia.—Loris Mélikoff describes the precautions taken along the Russian frontier to keep out the plague from Asiatic countries. The energetic efforts of the Prince of Oldenbourg, it would seem, have overcome almost insurmountable difficulties and made it possible for Europe to consider herself free from invasion from the side of Russia.—*Le Bulletin Médical*, August 29, 1900.

Medicine, September, 1900.

Suggestion without Hypnotism as a Therapeutic Agent.—Harold N. Moyer believes that suggestion, well directed, and above all patiently and systematically applied, forms a very important element in the treatment of many diseased states. Hypnosis, on the contrary, has many objectionable features. It is by no means easily induced, excepting in individuals with very unstable nervous systems, and in these it is quite certain that the effects are harmful. There is not a little evidence that goes to show that suggestion may be invoked just as efficiently without hypnosis as with it, but it would seem that the more self-consciousness is in abeyance the more efficient the suggestion. However, when the patient's own consciousness comes to the aid of the person making the suggestion, there is a possibility that suggestion may be more efficient without the hypnotic state. If an individual comes to a physician, for example, in the full belief that the physician is in possession of a remedy or a treatment that will infallibly cure a certain trouble, undoubtedly the effect on the patient's mind of suggestion along the lines of this thought is more efficient when the person is conscious than if he were in a hypnotic state. On the contrary, if the patient were opposed to the suggestion, it is self-evident that hypnosis, if it can be induced, would lend additional aid in making the suggestion operative.

Bone Food.—B. T. Whitmore suggests the ingestion of bone flour as a reparative food or means of supplying the phosphates needed to repair the phosphatic elements which are wasted in the economy of life. It is prepared from the larger bones of sound beef cattle. The bones are thoroughly cleaned of all muscular and tendinous tissue, dried, and ground. The resulting product is a fine powder devoid of taste and odor, which will keep indefinitely. It is given in admixture with other foods in such proportion as will serve to bring them up to the standard phosphatic supply. It may be mixed with any food article sufficiently glutinous to hold it in admixture, or it may be taken in suspension in milk or water. It is not intended to take the place of the various hypophosphites as a remedy, but as a dietetic agent is will frequently make the administration of the hypophosphites unnecessary.

Decinormal Salt Solution in the Treatment of Hemorrhage in Typhoid Fever.—C. H. Anderson reports in full one case out of five which were treated with transfusions of decinormal salt solution in the United States General Hospital at Fortress Monroe. In this case, of a corporal of the Illinois Volunteer Infantry, transfusion was performed several times, when the patient had collapsed from hemorrhages. He rallied well after each, and finally recovered. The author says that the mortality from typhoid fever accompanied by hemorrhage is very great, and transfusion should be done in every case. In the case reported it was done in a tent, without antiseptic and aseptic material, and with no conveniences with which to do careful work.

The Weather, Sunshine, and Infectious Diseases.—J. Ruhemann divides the meteorological conditions influencing disease curves into two general groups (1) Those acting principally on the individual, involving mainly the question of heat abstraction and comprising the atmospheric temperature, absolute and relative humidity, the direction

and rate of air currents, and the rain- and snow-fall; (2) The element of sunshine, which is the factor having most to do with ectogenous bacterial growth. Barometric pressure is not mentioned, for although not without its effect on man it does not hold any directly causative relationship to disease. Of these two groups the latter is by far the most important, and to a very marked degree controls the activity of bacterial life, so that the law may be laid down that the average of hours of sunshine for any season is in inverse proportion to the amount of infectious disease. This relation is, however, not synchronous but postponed, owing to the fact that allowance must be made for the periods of incubation, and in comparing statistics the periods contrasted must be taken from corresponding seasons of the year. Thus a week in March may show the same sunshine factor as one in October and yet the disease coefficient be much higher, since all winter long the weather has been dark, and therefore the conditions have been more favorable for the bacterial flora than during the light, sunshiny summer months.

Hydrotherapy in Gynæcological and Obstetrical Practice.—Ödön Tuszkai employs hydrotherapy under four different forms in the treatment of acute and chronic disease of the female pelvic contents. These are sitz-baths, irrigations, packs or compresses, and continuous application of heat or cold by means of water coils. Of these the sitz-bath is the most widely applicable and useful; the portion immersed should be from the middle of the thighs to the umbilicus. The effect of such a cold bath is to produce plethora of the cerebral vessels with attendant eye symptoms, buzzing in the ears, dizziness, increased respiratory and cardiac activity, with a pulse first rapid and irregular and then slow. The cause of these symptoms is the strong vaso-constriction due to reflex stimulation of the splanchnic nerves and which produces a local drop in temperature and reduced blood current at the surface, with the opposite effects at the periphery and in the interior. This is the result of a bath of short duration (five or six minutes), which is indicated in all conditions of atony, relaxation, etc., when there is no inflammation; if, however, it be continued for from fifteen to twenty minutes, contraction of the deep vessels and hyperæmia of surface take place. Warm sitz-baths produce superficial congestion and anæmia of the pelvic viscera, but here the reaction sets in much sooner than with the cold applications and a state of great relaxation supervenes, which contraindicates the procedure in any conditions in which congestion or hemorrhage is to be feared.

Russki Arkhiv de Patologii, May 31 and June 30, 1900.

The Effect of Repeated Injections of Toxins upon Nutritive Exchanges.—K. Dmitrievski obtained the following results by experimentation: (1) Pyocyanic toxin. In animals previously starved, nitrogen, urea, phosphorus, and chlorine were considerably increased after the first and slightly increased after the second and third dose. The first dose caused a notable loss of weight, the second and third a lessened diminution and for a lessened duration. In animals previously well nourished, four to five doses produced a condition of immunization, the modifications in weight and in the amount of nitrogen becoming less and less marked after each injection. (2) Toxin of bacillus coli communis. The modifications in weight, nitrogen, phosphoric oxide, and chlorine are about the same as in the case of pyocyanic toxin. (3) Diphtheritic toxin. In starved animals the first dose causes a loss of weight and an increase in disassimilation with hyperazoturia and hyperphosphaturia. The increase of nitrogen and phosphoric oxide is less than in the preceding experiments. Chlorine is increased. After the second and third injections, the percentage of nitrogen and phosphoric oxide is not increased so much as before, but the chlorine is augmented in amount. In well-fed animals the modifications of nitrogen become less and less marked. Hyperleucocytosis was found after each injection.

Cutaneous Hypæsthesia in Tabes.—Dr. Grebner, from the result of the examination of fifty-two patients, states that hypæsthesia always originates in two foci, corresponding to the third dorsal and the first sacral nerves, and is limited to the peripheral distribution of the posterior roots. From these two foci the affection is propagated above and below to the neighboring posterior roots. The upper focus is the one most frequently affected. The upper roots of the nuchis (from the fifth cervical nerve) are unaffected, even in advanced stages of the disease. This regularity in the occurrence and distribution of the hypæsthesia depends upon the structural differences in the segments of the spinal cord. Wherever there is ataxia, hypæsthesia is found. The skin covering the ataxic articulations is not necessarily hypæsthetic. The author found no improvement of articular hypæsthesia in cases in which improvement of the ataxia had been brought about by retraining of the muscles.

A Study of Immunity.—Professor Savchenko instituted a number of experiments with a view of ascertaining the correctness of M. Gabritschewsky's statement that the natural immunity of animals (guinea-pigs) against the spirillum is due to the rapid formation of specific bactericidal substances at the seat of inoculation. The experiments appear to disprove this statement, for the spirilla disappear as a result of a slow phagocytosis, the uninuclear cells almost exclusively performing the part of phagocytes. Even in vitro we can see that leucocytes containing immunizing substances are endowed with energetic properties of positive chemotaxis toward spirilla. The latest experiments demonstrate that immunizing substances may exist in the blood, without acting directly upon the spirilla, the action being through the agency of cells.

Clinical Study of Gout.—A. Svoechotoff holds that gout is due to auto-intoxication by the abnormal products of metabolism. The bases are probably closely allied to uric acid. The amount of urine and of urea diminishes, and that of uric acid increases during an attack. The vaso-motor system probably undergoes modifications during an attack; there is spasmodic contraction of the smaller vessels. Uric acid appears in the affected joints in the form of needle-shaped crystals of the biurate of sodium, and not in the form of globules. During the disease the kidneys may allow albumin to filter through without clinically appearing to affect the renal tissue. The seat of the gouty deposits probably depends upon nutritional changes in the tissues and enfeebled circulation. Surgical intervention is often imperative in gout.

Mycotic-Embolic Aneurism.—Oscar Ling describes the case of a youth, aged nineteen years, suffering from cryptogenic septicopyæmia and septic endocarditis. A pulsating tumor was found at the left elbow, and after the patient's death it was examined and judged to be a mycotic-embolic aneurism formed after a rupture. An embolus was found at the point of division of the artery; there were destruction of the internal, the elastic, and the median muscular coats, rupture of the adventitia, and dilatation, and the mass of micrococci foramed in the aneurism was similar to those found in the valves of the heart.

Anatomical Researches in Regard to the Cæcum and its Appendix.—Giullano Peronidi, from the study of the cæcal region in fifty cadavers, reaches the following conclusions: that the cæcum in eighty-three per cent. of the cases is situated in the lower part of the right iliac fossa. Next in order of frequency, its situation is in the middle or superior third of the iliac fossa; and next in the pelvic cavity. In three cases it was in the umbilical region, in one in the lumbar fossa. Its direction is usually the following: its axis is obliquely to the right, upward, and backward. In three cases it was vertical, in two transverse. Its serous covering was complete in seventy-five per cent. of the cases; its length varied from 6 to 10 cm., its breadth from 3 to 10 cm. The appendix was in the majority of cases cylindrical, vertical, and within the cæcum. In ten cases it was retro-cæcal; its average length was 7.6 cm. and breadth 5 cm. In one case the meso-appendix formed a pouch; in one, the ileo-appendicular fold was greatly developed; in one this fold was absent and its place taken by a rounded depression. The author claims to be the first person to call attention to these interesting characteristics.

Osteoplastic Amputations.—Z. Samfirescu describes a process to be used in the case of amputations in the continuity of the long bones of the extremities. It consists in the formation of an osteo-periosteal segment which is closely applied to the surface of the amputated bone, and which undoubtedly becomes joined to it later, in the same way that soft tissues unite together. The adaptation and consolidation of such a diaphyseal segment at the extremity of the amputated limb will make a stump as solid as the limb itself, with tissues equally diaphyseal. The author claims that in the case of children the bone, if treated in this way, will not grow after amputation; as all surgeons know, the growth of bone beyond the soft tissues in the end of the stump is an inconvenient occurrence which frequently takes place. The stump after this process can at once be

placed in an artificial limb, and it will, moreover, not be sensitive to changes of temperature, as are stumps formed according to the classic methods.

Pneumotomy with Resection of Ribs.—Michel Christovitch describes the case of a young man in whose lung had lodged the bullet from a revolver. On the sixth day after receiving the wound his condition was so grave that an operation was decided on. An exploratory puncture in the seventh left intercostal space showed an effusion of blood and pus. Three centimetres of the sixth rib were resected, and the ball was felt by the finger introduced into the wound. The fifth and sixth ribs were then resected, the pleura and lung incised, and the bullet was removed together with blood, pus, and three sphacelated pieces of lung tissue. Absorbent gauze stopped the hemorrhage, drainage was secured, the wound sutured and dressed, and ether and artificial serum injections were administered and repeated for two days. The operation lasted twenty minutes only. The patient was completely cured at the end of two months, with no fistula.

Abdominal Hysterectomy.—E. Quénu and L. Louquet thus sum up their study of the subject: Total abdominal castration for neoplasms of the appendages is legitimate, and not dangerous. It possesses great technical advantages, and prevents many post-operative accidents, such as intestinal occlusion. It is indicated in cases of ovarian cysts and tumors complicated by uterine, peri-uterine, and tubal inflammatory lesions, or those complicated by neoplastic degeneration of the uterus, and in bilateral ovarian cysts and tumors, when the size, friability, or situation of the pedicle presents difficulties as to hæmostasis. It is contra-indicated in cases of unilateral cyst in a young woman; when the uterus is healthy, and the manipulation of the pedicles easy; in cases of bilateral lesions of the appendages, and in cases in which a good treatment of the pedicle can be obtained by some easier process.

Familial Symmetrical Lipoma of the Plantar Arch.—Charles Féré describes the occurrence of tumors of the feet in two women, cousins. This cannot be ascribed to heredity, but must be classed as "familial." There was an arthritic and cancerous family history, and in both cases a markedly nervous previous personal history. In one patient there was herpes zoster of the lower part of the left leg and outer side of the foot, and this affection, in fact, was the occasion of the physician's attention being drawn to the lipoma of the plantar arch, which the patient asserted had been there for twenty years. Her sister had a similar growth on her foot.

Revue de Médecine, July 10, 1900.

Gastro-Intestinal Affections due to Neuroses.—M. Dubois writes of cases of gastro-intestinal dypsepsia, due to purely nervous conditions. In hundreds of these cases he has obtained a cure by making the patients abandon the restricted diet upon which they had been placed, sending them to bed in a sort of rest cure, keeping them upon a milk diet for a few days, and then suddenly causing them to return to three full meals a day of food chosen haphazard, or according to taste. The chief thing is to convince them that their trouble is cerebral, and does not come from gastro-intestinal disease, and their recovery is then immediate. The gastro-intestinal tract is peculiarly under the influence of the nervous system, and in psychotherapy is found the best treatment for the greater part of disorders supposed to indicate local lesions.

The "Coup-de-Foudre."—Charles Féré writes of the coup-de-foudre or "thunderbolt," a term used in French literature to signify what we might translate "love at first sight," were it not that love in its higher manifestations would appear to be absent. The author gives examples of the condition, which seems to be a symptom of degeneracy, of hallucinations of memory, and in especial of epilepsy and of neurasthenia. This explosive form of affection he thinks should be considered a symptom of morbid emotion, of nervous disorder, rather than a celestial inspiration to be followed at all hazards.

The Nasal Crisis in Tabes.—Henri Jullian describes this condition, which is characterized by an attack of sneezing with nasal paræsthesia, preceded by subjective symptoms in the region of the fifth nerve, consisting in a strange sensation of constriction and stiffness of the cheek and neck. The nostril of the same side suddenly appears to be occluded, and the sneezing follows. There is no especial increase of secretion. The crisis is undoubtedly due to the tabes.

Tuberculosis and its Open-Air Treatment in Normandy.—By Raoul Brunon.

Archives Générales de Médecine, August, 1900.

Is Scorbutus an Infectious and Contagious Disease?—H. Turner says that in Russia, in 1899, during an outbreak of this disease, physicians were struck by the following facts which seem to point to contagion: The epidemic character of the malady; its presence in certain villages and its absence from other villages, not far removed, but having no communication with the first; the large number of persons in easy circumstances attacked by the disease, who either were obliged to live in the midst of the epidemic or to come in daily contact with the sick. The author adduces a number of cases and facts which tend to prove that the disease is infectious, that isolation, even without special hygienic precautions, prevents its spread, and that salt meat and absence of vegetable diet are not the only causes. The microscope has not as yet discovered a specific agent for scorbutus, but it may do so with improved technique; and meanwhile there is every reason to isolate the patients. Writers of the sixteenth and seventeenth centuries thought the disease contagious. The Nansen party escaped it entirely, in spite of cold, insufficient diet, and absence of fresh food for sixteen months.

Spontaneous Dilatations and Ruptures of the Gall Bladder in Adhesive Supra-Umbilical Peritonitis.—A. Machard reports a case of this fatal accident. Obstruction of the cystic canal or ductus cholodechus by foreign bodies is not a necessary coudition to dilatation of the gall bladder; in the case under discussion it was produced by peritoneal adhesions which had obstructed the cystic canal. Hydrops of the gall bladder occurred, and the walls, weakened by infection due to stasis caused by the peritonitis, were unable to resist the internal pressure, and were ruptured. The best treatment for this condition is cholecystostomy with abouchement outside of the gall bladder. This insures drainage, and permits of direct antisepsis. It is also a rapid procedure. There is, to be sure, the drawback of a biliary or mucous fistula, but cholecystectomy or suture of the walls can be performed later when all danger of infection is over.

Researches in Regard to Arterial Pressure in Chloroform and Ether Anæsthesia.—Simon Duplay and Louis Hallion hold that death under anæsthesia is due to a fall in arterial pressure. Hence it would be of the utmost importance to be able to estimate the degree of pressure at every step of the anæsthesia; for, that known, it would be easy to direct the proper amount of intoxication and keep it within the limits of safety. In dogs, which are more liable to accidents under chloroform than are human beings, the anæsthetic can be given with absolute safety provided that a manometer be placed on an artery and carefully watched. The authors hope soon to be able to show that an exact estimation of arterial pressure during anæsthesia is not only desirable but very possible.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE THIRTEENTH MEDICAL CONGRESS.

PARIS, August 18, 1900.

THE Thirteenth International Medical Congress in Paris is now a thing of the past, and yet it is hard to form as yet a just appreciation of the work accomplished by its members. Dr. Chauffard's report, which was read at the opening session held in the Salle des Fêtes on the Champ de Mars, indicated that there were 6,000 members and delegates; 2,000 Frenchmen, 750 Russians, 570 Germans, 350 Americans, 330 Italians, 220 Spaniards. Though Dr. Chauffard does not seem to have mentioned the number of the English contingent, it was 220 strong, a very small number comparatively, due, however, to the condition of affairs in the British empire and to the slight degree of

tension existing between the two nations. There were 250 reports inscribed to be read, and 1,200 communications, a great many of which are signed by the most illustrious names in the medical line. Dr. Chauffard spoke also of the difference between this congress and the first one held in Paris in 1867, when there were 333 French members and 589 foreigners.

This opening session was to have been honored by the presence of President Loubet, but on account of the assassination of the King of Italy he did not come. The Salle des Fêtes is a large, circular hall, gaudily decorated, erected inside the Palais des Machines, a relic of the 1889 exhibition, and its size prevented one from hearing most of the speeches. The first was by Professor Lannelongue, the president of the congress, who spoke well and was much applauded. I happened to be seated next to one of his former colleagues of the internate, an honorary surgeon of the hospitals, and he told me that in his youth Dr. Lannelongue had been somewhat like Demosthenes, afflicted with a slight impediment in his speech. No trace of it exists at present, and his voice was heard better than any other. Dr. Lannelongue paid a tribute to the wonderful progress made in recent years in determining the causes of disease, and then compared the result of recent efforts to the discovery of those mysterious undulations of rays which exist in the solar spectrum from the red to and beyond the ultra-violet. Science was slowly transforming the civilization of the present day, and to bring forth its best fruits the seeker should not remain alone and isolated, but all should put their shoulders to the wheel and work together. One of the great principles of modern medical science was the cultivation of man's bodily health, and in the seeking after the knowledge needful to this it was necessary to be guided by a light akin to that of the miner in his progress through subterranean passages. Modern processes of investigation, more perfect, more accurate, would replace little by little the older forms; a new nomenclature of diseases and medical terms would render the interchange of ideas more easy, though a universal language could not as yet be established.

Dr. Lannelongue concluded by welcoming the various delegates and foreign members, and ended his speech by citing the words that the celebrated Bouillaud, the heart specialist, spoke at the first congress: "Thanks to you, my whole life has received at last its crown. I carry you henceforth in my heart, and you will live there till it stops beating."

Dr. von Bergmann, German delegate, Dr. Albert from Austria, Dr. Preisz from Hungary, Surgeon-General Sternberg, delegate from the United States, Sir William MacCormac, delegate from Great Britain, and Dr. Reverdin, of Geneva, made speeches. The last address made was by Professor Virchow who spoke on "Infection and Traumatism."

On Friday evening Dr. Pinard, president of the Obstetrical section, and Professor Terner of the Gynæcological section gave a dinner to one hundred and twenty members of those two sections, at the Grand Hotel. All the notable men in these specialties were present, and speeches and toasts were made in French, English, German, and Italian. After the dinner, which took place in the apartment called the Zodiac Hall, a reception, to which the ladies had been invited, was held.

Dr. Lannelongue's reception was the great social festivity of the congress. The number of invitations was, however, limited, not more than twelve hundred of these being sent out, so far as I could judge. This reception took place on Friday at the Galérie des Champs Elysées, and a musical entertainment was furnished. The close of the evening was a dance called the "Danse des Nations," undertaken by four young pupils of the opera, dressed respectively as a Breton peasant, an Italian, a Spanish girl, and a Russian peasant. Some thirty or forty American physicians were present with their wives and daughters.

Professor Landouzy gave a dinner to the therapeutists at the Marguery restaurant, a place which is famous the world over for its excellent cooking. The dinner took place in the large hall reserved for such festivities. Mme. Almé, of the Français, sang some delightful old French songs of the sixteenth, seventeenth, and eighteenth centuries. Professor Landouzy made a speech which was very much applauded. He said he had thought it well that therapeutists should pass from theory to practice; that this dinner was a "leçon de choses," a practical lesson, whereby the needs of the inner man could be satisfied. He spoke a few words about vegetarian diet, and showed how the menu was a complete refutation of the principles of the vegetarians.

On Monday night a social gathering offered by the members of the committee was to take place in the gardens of the Luxembourg, but on account of the weather it was resolved to hold it in the palace. Eight thousand invitations had been sent out, and as a certain number of members brought their families, and even acquaintances it would seem, the result was that there was an awful crush, and a certain number of notable medical men, who should have had reserved seats, left the place in sheer disgust. A musical and theatrical programme had been gotten up by Dr. Pozzi, and there was singing by Fongère, of the Opéra Comique, who rendered "Les Saisons," by Massé. Mme. Litvinne, of the Opéra, sang an air from "Tristan and Isolde"; M. Renaud, also of the Opéra, sang "The Willows are Weeping," by Erlänger, and Mounet-Sully recited some poems. The entertainment was certainly most brilliant.

On Friday afternoon the reception of the President of the Republic took place at the Elysée. A large crowd had gathered in the Faubourg St. Honoré, and only a few were allowed to enter at one time. The back of the garden, which fronts on the Avenue Gabriel and the Champs Elysées, had been transformed into a sort of stage, and dances of different epochs were given by ballet-dancers from the Opéra. The effect was striking. The weather was not, however, very propitious, and a slight shower would every now and then dampen everybody's spirits. There was such a large gathering in the gardens that it was difficult to get near the stage. The dances given were those of different epochs—the barbarian, the Greek, the Roman, and so forth.

On Saturday the Municipal Council received the members at the Hôtel de Ville in the apartments intended for festivities.

On Thursday, the 9th of August, the last general assembly took place in the amphitheatre of the Sorbonne. The second general meeting had been but scantily attended, but this time there was a large gathering. Dr. Lannelongue presided, having at his right Dr. Callejá, dean of the Faculty of Medicine of Madrid, and on his left Professor Virchow. Dr. Lannelongue introduced Professor Albert, of Vienna, who read a discourse on the architecture of the bones of man and animals. The prize of 5,000 francs, which had been offered at the Congress of Moscow to the author of the best work done in medicine or hygiene of recent years, was awarded to Dr. Ramon y Cajál, of Madrid, whose work on neurology has been so extensive and important. It was next definitely announced that the fourteenth congress would be held in Madrid in the spring of 1903. The Spanish national hymn was then played; Dr. Callejá spoke a few words, and Professor Costojórena, a member of the official Spanish delegation, thanked the Congress on behalf of Madrid for having chosen that city.

LETTER FROM JAPAN.

(From our Special Correspondent.)

THE PLAGUE—HOSPITAL SHIPS OF THE JAPANESE RED CROSS—REPORT OF THE SURGEON-GENERAL OF THE JAPANESE NAVY—ADDRESS OF DR. H. L. WOOD TO THE NURSES.

TOKYO, August 16, 1900.

THE pest has been practically stamped out, and the more stringent measures have now been superseded by the usual precautionary ones. Great credit is due to the government, and especially to the sanitary bureau, in this emergency. Dr. Kitasato's Bacteriological Institute, or Institute for the Investigation of Infectious Diseases, has furnished a corps of well-trained medical men who have given scientific and painstaking assistance in different parts of the country. Japan will undoubtedly require to keep constant and vigilant watch upon her borders, especially in the open ports, as she is now in such intimate communication with endemic sources of infection from the plague and cholera, both of which have proven so virulent and fatal in Japan, as well as on account of her proximity to the field of military operations in China, and her being the asylum of so many refugees from all over that country.

Japan is now having a good opportunity of making use of the two fine Red Cross hospital ships, the *Hakuai Maru* and *Kosai Maru*, both of which have been commissioned for service in connection with the war in China. The *Hakuai Maru* sailed some time since and has already made one or two trips. Dr. Iwai, of the Red Cross Hospital in Tokyo, is in charge, while Dr. S. Suzuki is in charge of the *Kosai Maru*. These ships are thoroughly equipped, up-to-date vessels, and no doubt will prove a great boon to the suffering wounded of other nations as well as of Japan. In placing these vessels at the service of the allied fleets and army, Vice-Admiral Toya stated that these vessels are under the control of the war and navy department, being equipped and maintained entirely at the expense of the Japanese Red Cross Society, and that the regulations of the Hague Convention of July, 1899, relating to the Geneva Conference of August, 1864, as far as circumstances would allow should be observed. This act

has been highly appreciated by the different admirals in command, among whom Rear-Admiral Kempff, of the United States navy, has expressed special appreciation. Thus far the number of wounded has not been so great as to tax the resources at the disposal of the united fleets, but should the disturbance extend up the Yang-tze valley and throughout other parts of China it is probable that all the resources, including those of the Japanese, will scarcely prove sufficient. Sascho, in the southern coast, is the present hospital base.

There are already large numbers of refugees in Nagasaki, Kobe, and Yokohama, while the mountain and seaside resorts have also received considerable numbers.

The health of the various ports of Japan at the present time is good, and the same may be said of the health of the refugees.

The annual report of the health of the Japanese navy for 1897 has just made its appearance, and though referring to conditions existing three years ago is none the less of considerable interest. The total mean daily force in the service was 14,964, and the ratio of cases of disease and injury per 1,000 of the force was 822. The number of days' sickness per man was 20.38 and 24.78 days' sickness per patient, while the number of deaths was 8.37 per 1,000. Among the various classes of diseases tabulated, venereal diseases were the highest, being 167.4 per 1,000, diseases of the digestive system being 151.1, while those of the respiratory system were 95.36.

The following extracts are of interest. The "momme" is about a drachm in weight, 120 *m.* being equal to one pound avoirdupois.

"Diseases of the Respiratory System.—The number of cases comprised under this nomenclature was 1,427, which is in the ratio of 95.36 per 1,000 of force, showing an increase of 49.04 per 1,000 as compared with the previous year. The deaths numbered thirty, giving a ratio of 2.00 per 1,000 of force, which is a decrease of 0.84 per 1,000 in comparison with the previous year. The number of invalidings was 139, the ratio being 9.29 per 1,000 of force, and shows an increase of 4.38 per 1,000 in comparison with the previous year. Cases of phthisis under this heading have increased year by year and many lives have been sacrificed to this disease. An instruction for the prevention of phthisis was, therefore, issued in June of this year and the proper method of prevention was carried out, but the cases have increased in frequency since former years.

"Conscription.—The total number of volunteers who receive the physical examination as seamen-candidates levied in this year reached 5,664 persons (excluding seamen temporarily levied). Of the above number, 2,155 persons passed the examination and the remaining 3,509 persons were dismissed. The result of examination shows a ratio of 38 per 100 of persons qualified, while that of persons non-qualified gives a ratio of 62 per 100.

"Food.—The average daily amount of food supplied to each person was 391.29 *momme*, being an increase of 6.39 *m.* as compared with the previous year. Taking each article of food in detail, it will be found that the amount of bread given was increased by 10.84 *m.*, fresh meat by 2.43 *m.*, fresh fish by 2.9 *m.*, rice by 0.48 *m.*, fresh vegetables by 8.66 *m.*, soy by 0.03 *m.*, and vinegar by 0.07 *m.*, while the amount of hard biscuit diminished by 7.74 *m.*, preserved meat by 3.01 *m.*, preserved fish by 2.72 *m.*, beans by 0.29 *m.*, wheat flour by 2.19 *m.*, dried vegetables by 1.84 *m.*, dried fruits by 0.46 *m.*, roasted barley by 0.16 *m.*, sugar by 0.43 *m.*, oil by 0.03 *m.*, common salt by 0.11 *m.*, and fat by 0.12 *m.* The amount of albumens for each person decreased by 0.60 *m.*, fat by 0.25 *m.*, and carbohydrates by 1.34 *m.* as compared with the previous year. [The cost per person a day was 9 cents United States gold.]

"Body-Weight.—The average body-weight of 14,000 persons taken in March and 15,271 persons taken in September, of cadets, petty officers, and men was 15,630 *momme*, being an increase of 120 *m.* as compared with 15,510 *m.* of the previous year, and also being an increase of 520 *m.*, over what has been the average body-weight 15,110 *m.* of each person during the last thirteen years. Thus it shows an increase of 40 *m.* even compared with the average weight 15,590 *m.* of the year 1896, which was the highest average since the year 1884, when an estimate of the body-weight was first made."

Among the many distinguished visitors to Japan this year we have been favored with the presence of Dr. H. C. Wood, of the University of Pennsylvania, who with his wife and daughter are spending some weeks in sight-seeing. Dr. Wood while in Tokyo attended the graduating ceremony of the Nurses' Training-School of the Akasaku Hospital, of which Dr. W. N. Whitney is the founder and present head. Dr. Wood's address was characteristic and helpful. He pointed out the importance of the nurses' calling and of exactness and punctuality in the performance of her duties. Miss Letsu Ito, a graduate of the Methodist Episcopal Training-Home of Philadelphia, is in charge of the school.

THE HOSPITAL FOR SCARLET FEVER AND DIPHTHERIA PATIENTS.

To the Editor of the Medical Record.

Sir: During the past winter we have received many letters of inquiry in regard to the methods of quarantine and disinfection used at the Hospital for Scarlet Fever and Diphtheria Patients, and it has occurred to me that the best way of reaching those interested in our work is through the columns of your journal.

A brief description of the general arrangement of the institution is essential to the understanding of our methods. The hospital is, as many of your readers are aware, situated at the foot of East Sixteenth Street, the grounds extending on two sides to the water's edge. Many physicians believe this hospital to be connected with the city institutions for the treatment of contagious diseases, but such is not the case. It is a private corporation, controlled by its own board of governors, and is not connected with any other institution. The president of the board of health and one of the health commissioners are *ex-officio* members of the board. There is a regular visiting staff, but physicians in general are allowed to attend cases which they send to the hospital.

There are two pavilions separated from each other at their nearest point by a distance of thirty feet, the workings of which are entirely distinct. Each employs a separate medical staff, corps of nurses, cooks, chambermaids, etc., and has its own kitchen, dormitory, and nurses' rooms and office for the use of the physician in charge, in connection with which there is a well-equipped laboratory and drug room, and an observation room where doubtful cases can be isolated. The patients' quarters consist of a number of light, well-ventilated rooms communicating with a long corridor, at the end of which there is a sun-room. There is no ward, so that each patient has a private room. Convalescents can enjoy the open air from the roof, which is arranged to accommodate them. The laundry is in a building by itself. The disinfecting plant is also separated from the hospital and consists of a steam tank and formaldehyde chamber. In the former the steam is raised under pressure to a temperature of 230° F. and kept turned on for half an hour. If formaldehyde is used, the articles to be disinfected are exposed to the gas continuously for twelve hours.

Patients are carefully examined before being admitted, and if there is any question in regard to diagnosis they are placed in the observation room of the scarlet fever or diphtheria pavilion. The resident physician before entering the presence of the patient is required to wash his hands thoroughly with soap and water, followed by immersing them in bichloride solution 1:2,000. A gown is supplied which buttons closely around the neck, covering the collar and enveloping the body completely, just clearing the ground below. With this goes a cap arranged to cover the head and neck, exposing only the face. This, with a pair of rubber overshoes, completes the uniform. When he leaves the pavilion, the hands and face are disinfected thoroughly, and the mouth is cleansed with boric-acid solution. The attending physicians, whether of the regular hospital staff or specially employed by the patient, follow the same routine, and this is required of all visitors. Ladies, if admitted at all, are also required to remove their outer skirts before putting on the uniform.

The patients are not allowed to leave until free from contagion. Scarlet-fever cases are examined repeatedly, particular attention being given to the feet, which are sometimes slow and troublesome in desquamating. The scalp requires watching, as does also the external auditory meatus, which is often found filled with desquamated epithelium in cases otherwise free from contagion. For the diphtheria cases we require two clear cultures on successive days before they are considered ready to discharge. The disinfection is the same in both pavilions, except that scarlet-fever patients, during the week previous to time of probable discharge, have their ears irrigated with bichloride solution 1:8,000 and the scalp shampooed on alternate days.

On the day of discharge the following routine is adopted for all adults unless there is some contraindication (for children special instructions are given in each case): (1) The ears are irrigated with bichloride solution, 1:8,000. (2) The scalp is shampooed with soap and water. (3) The scalp is shampooed with bichloride solution, 1:2,000. (4) A tub bath is given of soap and water. (5) A tub bath is given of bichloride solution, 1:8,000, for twenty minutes. (6) A sponge bath is given of bichloride solution, 1:2,000. (7) The bichloride is sponged off with sterile water. (8) A nasal spray is given of bichloride solution, 1:8,000. (9) The mouth is cleansed with saturated solution of boric acid.

For convenience is used a suite of three communicating rooms known as the discharge rooms Nos. 1, 2, and 3.

The first room is entered from the corridor, and here the hospital clothing is left. In No. 2 the patient is subjected to the process of disinfection. In No. 3 he puts on his freshly disinfected clothing. There is a "discharge door" in this room so arranged that he can leave the hospital without again passing through the corridor.

All clothing that can be washed is disinfected with steam. For articles that will not stand this treatment is used formaldehyde gas. Books and papers are subjected to steam, although it is necessary first to remove the leather covers from the former. Beyond a slight blurring of the writing no damage is done. Toilet articles are treated in the same way, but jewelry, such as rings, pins, etc., are disinfected with pure carbolic acid. Watches are exposed to formaldehyde gas, which disinfects them satisfactorily.

So far as we are able to learn no case of contagion has ever been traced to patients that have been discharged from our institution, and it is quite certain that never in the history of the hospital has a case of scarlet fever developed in the diphtheria pavilion or vice versa.

EDWARD L. KELLOGG, M.D.,
Resident Physician.

NEW YORK.

THE SPECTACLE AND EYE-GLASS HABIT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of August 4th was an extract from an article by me, entitled "The Spectacle and Eye-Glass Habit." In the issue of August 18th, Dr. T. T. Blaise, of Mason City, Ia., criticises the ideas expressed in that article, finding them unorthodox.

Dr. Blaise objects to the statement: "Wearing spectacles and eye-glasses out of doors is always a disfigurement, often an injury, seldom a necessity"; and says: "As concerns the disfigurement, it suffices to say that much of this can be obviated by the proper regard for cosmetic effects. There is no doubt that a face can be made to look ludicrous or comely, the effect produced depending chiefly on the oculist's knowledge of symmetry, harmony, and the angular or pleasing relation of lines and forms."

In spite of what Dr. Blaise says every practitioner knows that glasses are and always will be a disfigurement, and that most young and middle-aged women seriously object to any kind of them. Spectacles are a constant butt for the caricaturists, a cause of mirth to the thoughtless, and the prevailing and widespread degeneracy of the spectacle habit, particularly in children, invites the profound pity and inquiry of the thoughtful and observing, for the failings and imperfections of the eye are more quickly and certainly transmitted through heredity than those of any other part of the body, and the worst of this is that it hurts most the intellectual, the very top of civilization. If the generally accepted teachings of ophthalmology are true, then the eyes of Christendom are in a parlous state.

Dr. Blaise says: "It is not necessary to state that an anomalous or ametropic eye, which cannot be restored by operative or other means to a normal state, needs a support as much as a short leg needs a high heel, etc., and what is more potent and true is, that it needs it as long as that abnormality exists; indoors or out of doors, or wherever vision is desired."

The doctor probably means: All persons with farsightedness, nearsightedness, or astigmatism should wear glasses all the time, just as every man with a short leg needs a high heel.

About ninety-nine out of a hundred persons are ametropic, have some imperfection, when properly examined. About eighty or ninety of these are farsighted, to say nothing of those with astigmatism and nearsightedness. Now, if Dr. Blaise is right, nearly everybody ought to wear glasses all the time.

Dr. Blaise has confused function with structure. If an eye is imperfect or ametropic the focussing mechanism is proportionately strong and usually makes functional compensation. Nothing of this kind can take place in a leg structurally short. It is useless to discuss such a comparison, for, the basic fact in the problem of fitting glasses is one of function rather than of structure, although it does concern both. The imperfections of the eye give trouble more like a tired, weak leg than like a short one.

The doctor says: "It cannot be doubted that an eye having the proper correction will feel strained when the correcting lens is removed, as would the short leg when the heel is removed from the boot; but this Dr. Jenkins declares, with an unheard-of sweeping statement, to be "because they have wrong glasses."

On page 63 of volume lv. of the MEDICAL RECORD, the editor of that journal comments on Hartridge recommending hyperopes to leave their glasses off when not reading.

Another statement by Dr. Blaise: "To say that a lens correcting an error of refraction, a heterophoria, or any anomaly is only temporarily necessary, is reversing not only pure logic, but turns topsy-turvy the laws upon which hygiene, sanitation, and healing are based."

What are the laws spoken of with such definite certainty as though the principle and laws of gravitation in astronomy were under discussion? Medicine is still an inexact science, somewhat like agriculture or meteorology; obstetrics and, to an extent, surgery excepted.

Dr. Blaise says further "The individual with healthy normal eyes can as consistently and with as much comfort put on 3 D+ lenses when he goes into the street as the 3 D+ hyperope can remove his when he goes out-of-doors, barring what of custom, disregard, and disuse habit may have established."

The boot-heel again. Now, if "the individual with healthy normal eyes" puts on such glasses as Dr. Blaise speaks of and "goes into the street," he will have vertigo, nausea, and be miserably sick in a few hours, if not sooner. If a man is farsighted and is perfectly fitted for reading with such glasses as Dr. Blaise speaks of, he can read with them with comfort and be comfortable without them while on the street or out-of-doors. In this I am with Hartridge. The focussing muscles of eyes with farsightedness of 3 D are stronger and need much more work than those of perfect eyes. If the focussing muscles do not get their right exercise they will become weak or will atrophy. I take it that the error, "3 D+ hyperope," is a typographical one; again, that the writer means + 3 D.S. lenses.

Dr. Blaise is evidently following the antiquated and erroneous tables in the standard text-books, and seems not to have studied recent tables. The old tables are founded on the teaching that a perfect eye needs, for reading, an active focussing power of 4.5 D. It needs 3 D., possibly less. (See *Ophthalmic Record*, February, 1900, page 89.)

The fundamental and misleading error which pervades Dr. Blaise's criticism is that his elementary facts are wrong and, since it concerns one of the most useful and beautiful of the eternal verities, space will not be wasted in clearing his mistake, which is, indeed, a widespread one. He confuses function with structure in comparing spectacles to a raised boot-heel. Now spectacles are not essentially a prosthetic appliance, except, perhaps, after cataract operations. They are more orthopædic than prosthetic, for glasses correct rather than substitute. Do they not compensate, correct, and strengthen weakness and deformity? Glasses add and exalt, project and extend, our greatest sense, are its chief auxiliary. The telephone and microphone are also sensory aids. The telescope and microscope are but other forms of spectacles. The comparison of spectacles to a lengthened boot-heel is decidedly *outré*; as well think a telescope is like a high stilt. Such conceptions of glasses robs refraction of both professional and scientific dignity, makes it now an art, shortly to become a handicraft. To fit glasses properly one should well know the relationships of the eye to the other parts of life and their habits in both disease and health. Lack of this is the organic failing of many modern specialists.

The eye is so lively, nervous, and sentient that it really is not comparable to any other function except itself or the mind. It and its sight are so complex and so closely related to and intimate with the brain and thought that it seems of them, so much so that deep meditation on the eye and its function becomes philosophic rather than scientific.

The best ophthalmology is yet to be achieved, lies before and not behind us, and slavishness to authority and the past will not bring it. Medical science needs workers who see and think for themselves, men with clear vision anticipating wisdom; those who know what to do and how to do it, rather than they who know what has been done and who did it. We must be whole-souled doubters, for many things which pass current are but falsehoods and counterfeits. We too readily believe authorities. Scientific thought should be used on all questions alike. This can be done only by those schooled in using thought in a scientific way. "Prove all things and hold fast that which is good."

NORBURNE B. JENKINS, M.D.

CHICAGO.

An African Remedy for Dysentery.—The Kafirs and Zulus make use of the root of the geranium, of which there is said to be a number of varieties, all, however, of equal therapeutic efficacy, in South Africa, in the treatment of dysentery. They simply chew the root, but the British army surgeons give it in the form of a decoction in milk. The remedy is reported by those who have employed it to be a real specific, no failure to cure within thirty-six or forty-eight hours being recorded.

Therapeutic Hints.

Epileptiform Convulsions due to auto-intoxication.—

℞ Ext. chirettæ ..... gr. ij.
Leptandrin ..... gr. ss.
Podophyllin ..... gr. ½.
Euonymin ..... gr. ss.
Creosote (beechwood) ..... gr. ss.
M. ft. pil. No. 1. S. One such after each meal.

—Hare.

Tooth Powder.—

℞ Pulverized cereal ..... 75 parts.
Sodium borate ..... 18 "
Potassium chlorate ..... 7 "
Saccharin ..... q.s.
Flavor to taste.

—Fletcher.

Emulsion of Castor Oil.—

℞ Ol. ricini ..... ℥ i.
Gum acaciæ ..... ℥ ss.
Elix. saccharin ..... ♏ xx.
Ol. amygdal ..... ♏ ij.
Ol. carui ..... ♏ ij.
Aq. destil ..... ad ℥ ij.
M. Dissolve the gum in water, add the oil gradually, and lastly the flavoring.

—*Medical Times and Hospital Gazette*, August 11, 1900.

Seminal Emissions without marked erection.—

℞ Strychninæ sulph ..... gr. i.
Ac. phosphorici dil ..... ℥ ij.
M. S. Gtt. xxv. in water after meals.

—B. K. Twitchell.

Smoker's Gingivitis.—

℞ Salol 1
Tinct. catechu 4
Spir. menth. pip. ..... ad 120
M. ft. lotio. S. Teaspoonful in half a glass of tepid water as mouth wash.

Hair Tonic.—

℞ Pilocarpin. hydrochlorat ..... gr. v.
Ott. rosæ ..... ♏ viij.
Ol. rosmarini ..... ʒ iv.
Lin. cantharidis ..... ʒ iv.
Glycerini puri ..... ℥ i.
Ol. amygdalæ dulc ..... ℥ iij.
Spir. camphoræ ..... ℥ iij.
M. S. Rub well in, morning and night.

—Whitla.

Phthisical Cough.—

℞ Codein ..... gr. iv.
Ac. hydrochl. dil ..... ℥ ss.
Spir. chloroformi ..... ʒ iss.
Syr. limonis ..... ℥ i.
Aquam ..... ad ℥ iv.
M. ft. emuls. S. Teaspoonful at frequent intervals.

—Murrell.

Amenorrhœa in debilitated and anæmic states.—

℞ Hydrarg. chl. corros.,
Sodii arsenit.,
Strych. sulphat. ..... āā gr. i.
Potass. carbonat.,
Ferri sulphat. ..... āā gr. xxx.
M. ft. pil. No. lx. S. One after each meal.

—Lutaud.

Tuberculous Laryngitis.—

℞ Menthol.,
Ether. sulphurici,
Ol. pini sylvestris,
Tinct. iodi ..... āā ℥ ij.
Tincture benzoini co ..... ad ℥ ij.
M. S. Ten drops on an oro-nasal inhaler, to be worn as much of the time as possible.

—W. Fowler.

Epistaxis.—Puff-ball applied freely.—Whitla.

Suprarenal extract capsule will probably be found useful. It lessens bleeding during nasal operations. Hot water (110° F.) is useful either injected or applied as a swab. Peroxide of hydrogen may be left in position on a swab for fifteen minutes. In hæmophilia give calcium chloride and in purpura turpentine.—William Lamb.

Urticaria.—

℞ Ethyl alcohol,
Sulphuric ether,
Chloroform ..... āā 30. gm.
Menthol ..... 0.10 cgm.
M. S. Apply as lotion.

—Gaucher.

Menthol Vinegar.—

℞ Menthol ..... 3 gm.
Acid. acetici (crystal) ..... 8 "
Spt. vini rect. (sixty per cent.) ..... 100 "
M. Dissolve the menthol in the alcohol and add the acid. S. Half a teaspoonful in a wineglass of tepid water as a mouth wash or gargle.

Carious Teeth.—

℞ Menthol ..... 2. gm.
Camphor ..... 1. "
Cocaine ..... 0.50 "
M. Triturate to liquefaction. S. Introduce into the cavity a pledget of cotton wet with the solution every half-hour till relief.

Antineuralgic Lotion.—

℞ Menthol ..... 1.50 gm.
Cocaine hydroch ..... 0.50 "
Chloral hydrat ..... 10. "

—Galezowski.

Caffeine Mixture.—

℞ Caffeinæ,
Sod. salicylat ..... āā 1. gm.
Spartein. sulphat ..... 0.40 "
Ammon. acetat ..... 1. "
Aquæ destil ..... 50. "
M. S. Teaspoonful undiluted or in a little spirits.

—Capitan.

Rebellious Intermittent Fever.—

℞ Quininæ sulphat ..... 4. gm.
Ferro-potass. tartrat ..... 10. "
Acid. arsenosi ..... 0.10 cgm.
Aquæ destil ..... 300. gm.
M. S. The day following the attack a dessertspoonful of this solution is given every hour, the following day every three hours, and so on.

—Baccelli.

Amenorrhœa.—

℞ Strychninæ sulphat ..... 0.12 cgm.
Acidi oxalici ..... 0.60 "
Ferri peptonat.,
Manganesii lactat. ..... āā 8. gm.
Ext. colocynth. comp ..... 2. "
M. ft. cachets No. 60. S. One after each meal.

—H. C. Bloom.

Delirium Tremens.—

℞ Methylal ..... 5 gm.
Aq. destil ..... 20 "
M. S. Inject a syringeful three or four times a day, subsequently twice daily for five or six days.

—Fischer.

Anæmia in Phthisis.—

℞ Sulphur. loti ..... 10 gm.
Sacch. lact ..... 20 "
M. S. A pinch at beginning of each meal.

℞ Pulv. digitalis fol.,
Ferri lactat ..... āā 2 gm.
Ext. gentian ..... q.s.
M. ft. pil. No. xxx. S. Two pills daily.

—Von Székely.

Blennorrhagic Dysuria.—

℞ Sod. salicylat ..... 10. gm.
Ext. bellad ..... 0.30 cgm.
Aquæ ..... 195. gm.
Tinct. aurant. cort. amar ..... 5. "
M. S. Dessertspoonful every two to three hours.

—E. Gerbert.

Migrating Erysipelas in a child aged four years was cured in three weeks by tepid baths (120° F.).—A. Halipré.

To Cause Sleep.—Inject per rectum:

℞ Chloralamid. . ..... gr. xlv.
Ac. hydrochl. dil..... gtt. ij.
Spt. vini rect..... gtt. xv.
Aquæ destil..... ʒ iij.

—*Agenda Therapeutica.*

Dysmenorrhœa.—

℞ Asafœtidæ..... gr. ij.
Ext. valerian..... gr. i.
Ext. cannabis ind..... gr. ¼
M. For one pill. S. One three times a day.

—Lyon.

Pruritus Ani.—Inject into the bowel for several days in succession from one to two and a half drachms of the following:

℞ Ext. hamamelidis fld..... ʒ i.
Ext. ergotæ fld..... ʒ ij.
Ext. hydrastis fld..... ʒ ij.
Tinct. benzoini co..... ʒ ij.
Olei carbolisat. (five per cent.) ..... ʒ i.
M. S. Shake well before using.

Nasal Spray in acute catarrhal conditions.—

℞ Ac. carbol..... gr. viiss.
Ichthyol..... ʒ i.
Spir. vini rect..... ʒ iiss.
Aq. destil.....ad ʒ iij.
M. S. Use two or three times a day.

In Stomach Washing.—

℞ Sodii biborat..... ʒ ij.
Ac. salic..... ʒ ss.
Ac. borici.....ad ʒ iv.
M. S. Add a dessertspoonful to a quart of warm water.

Anaphrodisiac in gonorrhœa.—

℞ Ext. ergotæ fld..... ♏ xv.
Tinct. gelsemii..... ♏ v.
Potass. bromidi..... gr. xx.
Tinct. hyoscyami..... ♏ xxx.
Syr. aurantii.....q.s. ad ʒ ss.
M. S. Shake and take a dose at bedtime.

—Lydston.

Rachitis.—

℞ Phosphori..... gr. 1/60.
Solve in ol. oliv..... ʒ iiss.
Pulv. gummi arab..... gr. lxxv.
Syr. simplicis..... ♏ lxxv.
Aq. destil..... ʒ iiss.
M. S. One teaspoonful daily.

—Stewart.

Emphysema.—

℞ Potass. iod..... 10
Aquæ destil..... 300
M. S. Teaspoonful at each meal for twenty days of each month.

℞ Sodii arsenitis..... 0.10
Aquæ destil..... 300.
M. S. Teaspoonful three times a day for the other ten days.

—*Journ. de Méd.*

Chronic Alcoholism.—

℞ Zinci oxidi..... ʒ i.
Piperinæ..... ℈ i.
M. ft. pil. No. xx. S. One three or four times a day.

—Chapman.

Acute Alcoholism.—

℞ Tinct. capsici,
Tinct. zingiberis.....āā ʒ i.
Tinct. valerian. ammon.,
Tinct. gentianæ co.....āā ʒ i.
M. S. Dessertspoonful in a cup of hot water three or more times a day.

—Gerhard.

Anaphrodisiac.—Lupulin in gram doses at bedtime. —*Medical Times and Hospital Gazette.*

Thinness.—Avoid condiments, acids, sour fruits, salads, cabbage, coffee, turnips, sour wines, hot drinks, tobacco; take fatty meats and fatty foods, the crust of bread, pastry, beans, peas, nuts, sugars, honey, water; reside in the country and secure rest of mind as well as of body; take Fowler's solution in gradually increasing dose up to twenty drops.—Le Roy.

Tuberculosis of the Kidneys.—

℞ Ichthyol.,
Aq. destil.....āā 20
M. S. Ten drops increased up to seventy, taken in water after eating, to be continued for a long period.

—Goldberg.

Adynamia from withdrawing alcohol in habitués.—

℞ Spir. ammon. aromat..... ʒ ss.
Strychninæ..... gr. 1/30
At dose. Repeat every hour.

—Tyson.

Uræmic Asthma.—Morphine hypodermatically.—Ringer.

Pelvic Neuralgias.—Salicin gr. v.–xv. three times a day in cachet or capsule after meals, followed by a glass of water.—*Journ. de méd. de Paris.*

Gout.—In addition to the regular diet one and one-half pound of cherries, one pound of strawberries, or two pounds of grapes. Quinic acid acts by diminishing uric acid.—J. Weiss.

Post-Syphilitic Tabes.—Electrization of the spine and medulla oblongata; cauterization of the spine with the Paquelin every tenth to fourteenth day. Strychnine pills, atropine and morphine for the lancinating pains.—Tschirieff.

Pneumonia complicating influenza.—In the congestive stage give quinine and mercury with chalk; also fluid extract of ergot in doses of ♏ xx.; in the exudative stage quinine, digitalis, tincture of iron, and dilute hydrochloric acid; give stimulants for asthenic symptoms.—Latchford.

Sciatica.—Apply each night along the painful areas strong hydrochloric acid by means of a glass rod; then, when dry, cotton and a loose bandage; omit if redness or irritation ensues.—Bayliss.

Whooping-Cough.—Spray the nasal mucous membrane with cocaine, and apply to the nose and nasopharynx a two- or four-per-cent. solution of nitrate of silver; wash with a mild alkaline and antiseptic spray. —H. Coggeshall.

Juvenile Obesity.—Thyroid extract gr. iiss. three times a day, gradually increased to gr. vi. four times daily, for a boy of eight years, weighing one hundred and thirty pounds.—J. A. Love.

Bronchial Adenopathy.—Each morning some sulphurated water with warm milk. Cod-liver oil; arsenate of sodium (gr. 1/61 – 1/32) with meals, followed in fifteen days by phosphates. Two or three drops of tincture of belladonna and the same amount of alcoholic extract of aconite root as a calmative.

Asthma.—For the threatening attack paint the nasal mucous membrane as far back as possible with cocaine solution (1 : 20). If the attack is at its height, inject half a syringeful of a one-per-cent. morphine solution. Should the attack persist, repeat this injection. The remedies for the diathesis are potassium iodide, belladonna, and arsenic.—Dieulafoy.

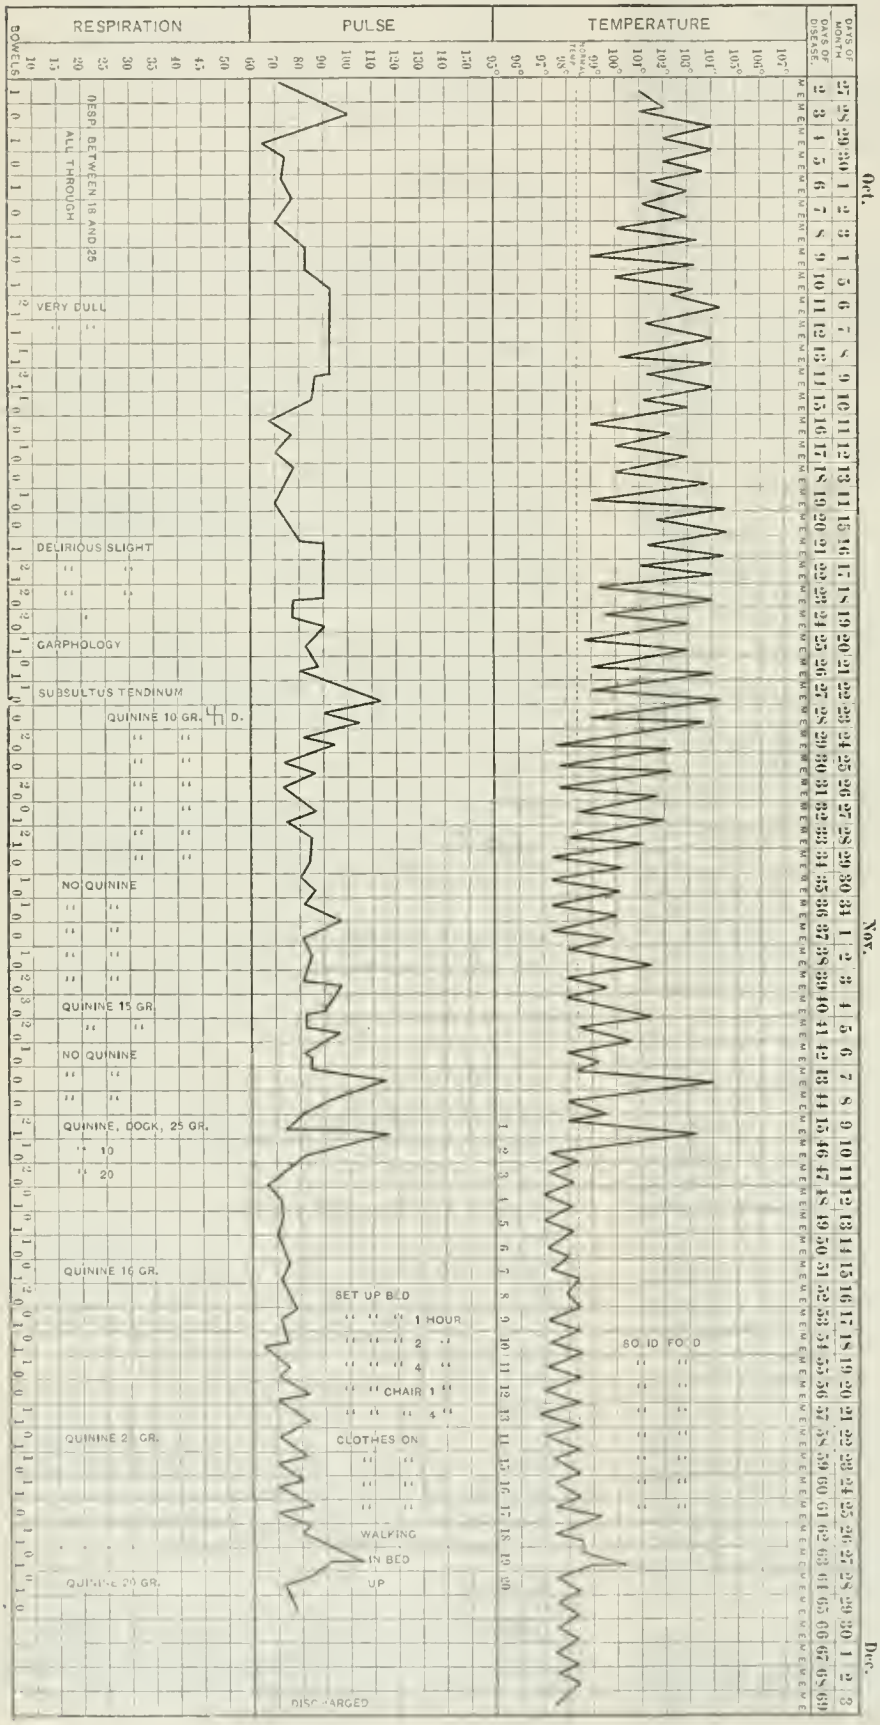
Mercolint is the name of the material recommended for shirts to be worn by anæmic or weakly subjects of syphilis, pregnant women, and infants who need a mercurial course. The cloth is impregnated with an ointment of ninety per cent. mercury, and each shirt contains from ten to fifty grains.—Blaschko.

Clinical Department.

MALARIA COEXISTING WITH TYPHOID FEVER.

By J. G. HANSON, M.D.,
NEW YORK.

THE coexistence of malarial and typhoid fever has been the subject of much discussion. W. G. Thompson, in 1893, writing of typho-malarial fever says: "The name typho-malarial fever must not imply a specific disease, but rather a combination or coexistence of two diseases, typhoid fever and malarial fever, in the same patient." While allowing that these diseases may coexist he further says: "To produce this fever there must be a double infection with the typhoid bacillus and the malarial plasmodium. Unfortunately, positive evidence that these two germs can coexist in the same individual has not yet been obtained, since the natural history of both germs has been studied for only a brief decade."



The following case, under my observation throughout its course, will be of interest in that it demonstrates positively the coexistence of malarial fever with typhoid fever, and bears evidence that the malarial element, while not wholly inactive during the period of typhoid infection, did not materially affect the course of the disease, but made itself more manifest during convalescence.

The patient, a male nurse, twenty-three years of age, of robust health and phlegmatic temperament, became ill during an epidemic of typhoid fever. He was the possessor of a fixed idea that if he should ever take to his bed because of sickness he would never recover, and he therefore carefully concealed his early symptoms. His dull and apathetic condition excited suspicion, and after much persuasion I succeeded in getting his temperature; it registered 102° F. He was taken off duty, but refused to go to bed. The following day, however, his temperature was 104 F., and he was forced to yield to treatment and obey the physician's orders. He presented the typical typhoid symptoms: the headache, pain in the lumbar region, the characteristic tongue, the mental hebetude, and later the low, muttering delirium and subsultus tendinum.

On the seventh day the

Widal reaction was present. The wide ranges of temperature in each twenty-four hours, noticeable throughout the disease, accompanied with sweating at fairly regular intervals, led to a belief that a malarial element might be present, though several careful blood examinations during the first three weeks failed to disclose the malarial organism. On the twenty-seventh day of the disease, however, the plasmodia malariæ of the tertian form were found in abundance. Up to this date the treatment had been as follows: sweeping out the intestinal tract with calomel and salines; salol in gr. viii. doses every four hours as an intestinal antiseptic; baths at 68° F., to reduce the temperature and strengthen the heart; and, for nourishment, liquid food every five hours.

On the day the malarial organisms were found, quinine in gr. x. doses was substituted for salol, and continued a week, then stopped. During the time it was given the temperature fell by lysis. Four days after quinine was discontinued the temperature went up to 101.4° F., falling, to rise on the second day following to 101.5° F., and on this day gr. xv. of quinine was given, and, as seen by the chart, the evening temperature fell, being nearly at normal on the forty-second day of the disease.

The next day (forty-third) the evening temperature registered 104° F., the patient having the chill, hot stage, and the sweating of malaria. An examination of the blood eight hours after the chill showed the malarial organisms in abundance.

In order better to observe the case, quinine was withheld, and after the usual interval in the tertian form of malaria, the temperature again went to 103° F. Quinine was then given after Dock's method, with most favorable results, the slight rise on the sixty-third day of the disease being due to indiscretion in diet. The patient was discharged as recovered sixty-nine days after admission.

Typhoid fever was the initial disease, and its symptoms predominated throughout its usual course, but with the period of defervescence we saw the malarial element, which had been masked, appearing in typical form; and while we are positive that it was present during the latter part of the attack, there is strong presumptive evidence that it developed early in the disease.

The accompanying chart gives the morning and evening temperatures, with the condition of the circulatory, respiratory, and intestinal apparatus during the course of the disease.

LARGE SUBDURAL ABSCESS AND ABSCESS OF THE BRAIN FOLLOWING A PENETRATING WOUND, WITH BUT SLIGHT PRESSURE SYMPTOMS.

By LOUIS J. MANDEL, M.D.,

BROOKLYN,

HOUSE SURGEON TO THE GERMAN HOSPITAL OF BROOKLYN.

C. B——, a male infant, was brought to the hospital on August 28th, by his mother, complaining of partial paralysis of the left arm, of irritability of temper, and of progressive loss of flesh and strength. There was a tumor mass, ovoid in shape and about the size of a robin's egg, on the right side of the skull, about one and one-half inches above the external auditory meatus, corresponding about to the anterior inferior angle of the parietal bone.

On questioning the mother, the following history was obtained: The family history was negative, both parents and other members of the immediate family being in good health; the patient was the youngest of a family of seven children. The child was bottle-fed, and his mother says he always had been in good health up to the time of the accident. About three and a half weeks before admission to the hospital the patient fell out of bed, striking the floor with considerable force, and landing head first upon a large wire nail, which entered his skull. The mother and the older sister of the child, attracted by its cries, rushed into the room, picked up the child, withdrew the nail, and carried the boy, who was bleeding quite freely, to the office of a neighboring physician. According to the mother's story, the physician made an examination of the child, assured her that the skull was not fractured, and that the injury was but a slight one. He then washed the wound and applied a piece of adhesive plaster, instructing her, she says, to return in the course of the week. She called again about a week later, and, after having again washed the child's scalp, the physician informed her that the wound was perfectly healed, and discharged the infant as cured.

The mother states that the child ever since the accident has progressively lost flesh and strength and grown more and more irritable. She, however, regarded these phenomena lightly, attributing them to the heat, and it was not until three days ago, when there simultaneously appeared the symptoms of a tumor on the right side of the head, of vomiting, and of paralysis of the left upper extremity, that she regarded the condition of the child as serious and consulted her regular medical attendant. After an examination of the child, the physician recommended operative interference as the only treatment for the relief of the symptoms. Three days after this consultation with her regular attendant the mother presented herself and child at the hospital.

The child was admitted to the children's ward of the hospital, and a physical examination showed the following: The general condition is poor, the patient is very much emaciated, the conjunctivæ and mucous membranes are pale, the patient vomits immediately after the ingestion of food, the bowels are constipated, and the child has an apathetic and stupid appearance.

Thorax: The ribs are prominent, the intercostal spaces deep, and palpation reveals a slightly developed rachitic rosary. The heart and lungs are normal; the pulse and respiration are regular, being respectively 125 and 25; the temperature is 100° F. The abdomen is prominent and distended, otherwise the examination of this part gives negative results. Extremities: The muscles are atrophied and flabby.

The head is normal in size; the anterior fontanelle is prominent and pulsating though of normal size. There is a tumor mass, ovoid in shape, about the size of a robin's egg, situated one and one-half inches above the external auditory meatus about at the anterior inferior angle of the parietal bone. The tumor is surrounded by an area of œdematous tissue one-half inch in width, and gives an impulse when the child cries, increasing at such times to one and a half times its normal size, the overlying skin becoming tense and shining. The tumor can readily be reduced into the cranial cavity, when there is felt a small, round hole in the bone, about three-eighths of an inch in diameter and occupying approximately the centre of the tumor mass. The skin overlying the tumor shows the scar of the former wound, which has an unhealthy appearance. The pupils are both dilated, the right more so than the left. The left pupil slowly reacts to light, the right does not. The left upper extremity is paralyzed and anæsthetic. There is, however, good function of the lower extremity on this side and only slight impairment of sensation of this limb and of the trunk on this side. There is no stiffness or rigidity of the muscles of the neck or back, and there is no hyperæsthesia. The skin is exceedingly hot and dry, and there is a marked difference in temperature between the paralyzed limb and its unaffected fellow.

Upon the history thus obtained and upon the findings of the physical examination, a diagnosis was made of primary compound depressed fracture of the skull, with subsequent necrosis of the depressed fragment, and abscess formation, this abscess being both intra- and extra-cranial, the two parts communicating with each other by means of the puncture wound in the bone; by its pressure upon the motor cortical area this abscess has caused paralysis of the opposite half of the body; the greatest amount of pressure was in that portion which controlled the motion of the upper extremity.

An unfavorable prognosis as to the success of operative interference in the present condition of the patient was given, but at the urgent request of the parents that the child be given this, its only chance of recovery, Dr. Weisbrod, one of the visiting surgeons, assisted by the house staff, trephined the infant's skull under chloroform narcosis. The skin flap was three-fourths of an inch in diameter, its base pointing downward and backward and its circumference encircling the base of the tumor. As soon as the flap was dissected back, pus in great quantity began to well out of the hole in the bone. A trephine one-half inch in diameter was set, and a button of bone was removed with great difficulty, the underlying thickened dura being a great deal more adherent than normally in a child of this age. The button of bone having been separated from the dura, the hole in the membrane was increased in size, and the pus, which was fairly thick and creamy, flowed freely, in all about fourteen ounces of pus being removed. The abscess cavity was drained with a strip of plain hemmed gauze, and the child was placed in bed on its right side so as to favor drainage.

On removal from the operating-room the child's temperature was 99.2° F.; pulse, 140; respiration, 24. The child had also regained complete control over the movements of the paralyzed limb and in every way seemed greatly improved, it being able to retain some liquid food which was fed to it in drachm doses; its pupils became regular and it seemed brighter and more cheerful. The wound was dressed fifteen hours after operation, the drain being removed, and six ounces of pus was drained from the cavity as the child was held on its right side.

The rally of the child was only transitory, for it soon began to grow worse again, refusing to take food; the palpebral fissures became widely dilated, marked nystagmus developed, and the child emitted sharp, short, penetrating shrieks. The respirations became irregular, the pulse rose rapidly, and the temperature was correspondingly high, these being just before death respectively 50, 180, and 106° F. The child died at 5 P.M. August 29th, twenty-two hours after the operation.

The autopsy disclosed the dura to be greatly thickened and the calvarium was removed with difficulty, efforts at separating the dura from the bone being futile, so that it had to be taken away with the skull cap. The brain thus exposed showed a large area of depression over the superior frontal and a portion of the anterior central convolutions, the area occupied by the subdural abscess. The brain tissue was greatly thinned and softened, and there was an abscess in the posterior portion of the superior frontal convolution which communicated with the lateral ventricle on the right side, which ventricle was greatly distended and filled with pus. Just anterior to this abscess there was a puncture wound made by the entrance of the nail into the skull.

From the above history, the results of the physical examination, and the disclosures of the autopsy, it is probable that early trephining and proper and careful treatment of the wound might have resulted in the recovery of the child; for, as was clearly brought out at the autopsy, the abscess in the brain did not communicate with the wound in its substance, nor did this wound communicate with the subdural abscess, from which it was walled off by stout adhesions.

The lesson of this case is that it is the duty of every practitioner to examine thoroughly under aseptic precautions every scalp wound and to satisfy himself beyond the shadow of a doubt that there is no fracture; or in case there is a fracture, he should see to it that it receives careful treatment at the hands of a surgeon.

A CASE OF PERVERSION OF SEXUAL INSTINCT.

By A. C. PANTON, M.D.,

PORTLAND, OREGON.

The following strange case presented itself lately in my service at Good Samaritan Hospital of this city: The patient was a farmer, aged sixty-eight years, family and personal history good. He was a soldier during the Civil War, and was married in 1865 to a woman who bore him four children. But love took wings when poverty entered the household, and the couple separated in 1883, the husband settling on a farm where he lived alone.

For four years nothing unusual took place in his life (so he says), but thirteen years ago, in order to gratify an abnormal sexual passion, he was prompted to perform a surgical operation upon himself. He thereupon sharpened his pocket-knife, and, with a slash, divided his scrotum into two lateral halves up to the penis. During his military career he had seen a surgeon sewing a wound, so, bearing in mind the method, he took a needle and common cotton thread, and with interrupted sutures united the divided skin of the front and back of the left half of his scrotum, and repeated the same operation on the right side, with the result that each testis now had a separate scrotal investment. He did not wash the wound, but "tied it up in the blood," and went on with his farming. Everything seems to have healed as kindly as if done under modern surgical asepsis.

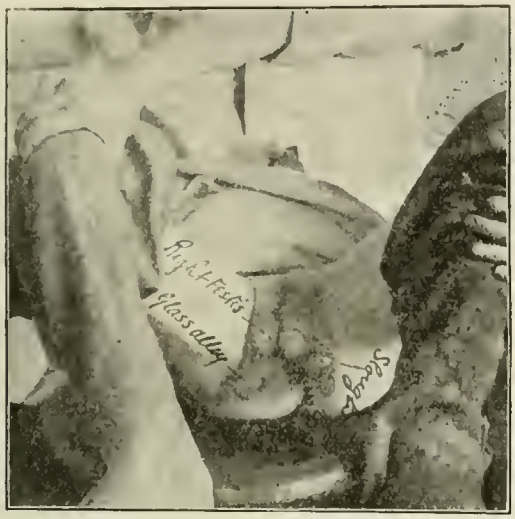
After this first experience, the knife with which this devotee sacrificed to Eros was in frequent requisition. As a rule, a small incision of one or other scrotum, or of the skin about the root of the penis, satisfied his cravings; but eight years ago he indulged in a startling and unique departure, in that he made a free incision into his right scrotum and inserted therein a glass marble or alley, about one inch in diameter, suturing the tissues over it. The operation was a success, the wound uniting firmly, but as time advanced, owing to its weight, this addition became pendulous, and, as seen in the accompanying illustration, hung from a pedicle about an inch in length. It seems, however, to have been quite satisfactory to its owner, who continued at intervals to incise himself, sometimes losing his self-control and cutting himself more freely than his cooler judgment would have approved. This last fact led to his coming under my notice. On July 20th last, he was brought to the hospital suffering from a severe wound of the left scrotum two inches long and two inches deep, upward toward the pubes, accompanied by such bleeding that he tied some cloths tightly about the mangled parts. But the scrotum became distended with blood, which again burst forth, and he removed his first bandage and applied tighter ones. This time the blood flowed no more, but his left scrotum became gangrenous.

When I first saw him his condition seemed rather desperate, as he was suffering from septic fever and the parts involved were in a foul and sloughing con-

dition. I had the wound dressed with hot boracic-acid solution, and put the man on supportive treatment.

It was with great difficulty that I obtained the preceding history. For some days he maintained that the hard mass, which turned out to be a marble, was a testicle that had been there all his life. But finally he confessed the truth, and stated that the pains which he had endured from these mutilations were enjoyable to him.

In a week the sloughs had separated and the swelling had subsided, and believing that it was not imperative



to make a supreme effort to save his left testis, I removed it, and also his glass alley, which was firmly encapsulated, and which being cut down upon was found to be a thing of beauty, with an elaborate spiral of red, green, and yellow colors in its interior.

It is remarkable that this humble operator with his dirty old jack-knife, dirty glass alley, etc., had such immunity from sepsis throughout a series of mutilations extending over a period of thirteen years.

Surgical Suggestions.

To Keep Cocaine.—

℞ Cocainæ hydrochl ..... gr. iv.
Acidi salicylici ..... gr. ss.
Aquæ destil ..... ʒ iij.
—*Journ. de Méd. de Paris.*

Vulvitis in Young Girls.—

℞ Salol ..... gr. ij.
Ol. theobr. ..... gr. xv.

To make a crayon 3 mm. in diameter. This is introduced without aid of speculum twice or three times a week till a cure results.—Comby.

Vulvitis.—

℞ Liq. plumbi subacet. ..... ʒ i.
Tinct. hyoscyami ..... ʒ ij.
Aquæ camphoræ ..... q.s. ad ℥ viij.
M. S. Apply.
—*Medical Standard.*

Rubber Gloves have in their favor the matter of convenience and the fact that they are more easily sterilized than the more absorbent skin of the hands. —E. Wormser.

To Sterilize Gloves.—Wash thoroughly with soda solution, inside and out, and hold for a minute or two over a gas flame or heater to dry. Dust the inside with sterilized soapstone; wrap each pair in a double layer of gauze. Lay on a towel and place in formic aldehyde sterilizer for two hours. Four or five sets may be prepared at a time. After putting on, dip in sublimate solution 1 : 1,000 for five minutes.—C. H. Richardson, in *Albany Medical Annals*, July, 1900.

Chilblains.—

℞ Spir. chloroformi ..... ʒ ij.
Lin. bellad. ..... ʒ ss.
Tinct. benzoini co. ..... ʒ ij.
Lin. saponis ..... ʒ iij.
M. S. Saturate a piece of sheet lint and apply.
—*Journ. A. M. A.*

Cholesteatoma.—

℞ Papain ..... ʒ i.
Ac. hydrochl. dil. ..... ♏ xv.
Aquam ..... ad ʒ i.
M. S. Instill into the ear and retain for at least half an hour.
—Yearsley.

Air Cauterization is the best treatment for inoperable nævi. The hot-air current should be passed over the tumor until incision shows the blood spaces to be empty and the part mummified.—Holländer.

Instruments after use should be cleaned with brush and sapolio, then boiled in plain or soda solution just before using. They should be kept under water to prevent exposure to the air.—C. H. Richardson.

Angina Epiglottidea Anterior is very often primary. Early scarification is advised, and iced ichthyol spray is of value in relieving the acute pain and reducing the inflammation. Steam inhalations are of service when iced sprays cannot be used.—C. F. Theisen.

The Gall Bladder is very tolerant of surgical manipulation. Over ninety per cent. of primary cancer of the organ is due to gall stones. Early operation reduces the mortality.—Roheson and Kehr.

Mortality of the wounded is greatly lessened by the modern small-calibre, small-arm projectile which now produces ninety per cent. of battle-field injuries.—Borden.

Aneurism of the entire right subclavian, of egg size, was cured by ligation of the axillary under the clavicle and of the common carotid close to the innominate trunk.

Lingual Tonsillar Abscess is a condition of extreme discomfort simulating œdema of the glottis. The swelling is at first hard, then fluctuating. Incision gives relief even when pus is not reached.—Frothingham.

Femoral Fracture in an infant was treated by flexing the limb on the abdomen, the foot being over the shoulder and retained by bandages. A loop of bandage was carried around the ankle and fastened to the rail of the cot. A good result followed.—J. D. Rice.

Cancer of the Vagina.—Pryor's radical operation has a surgical basis in the following principles: (*a*) The preliminary and preventive hæmostasis renders the field of operation comparatively dry, and there is less danger of transplantation of cancer-cells during the subsequent manipulations; (*b*) avoidance of injury to the cancerous field until hæmostasis is secured and the cancer charred; (*c*) there is removal of all organs in which recurrence is apt to take place from above downward; (*d*) establishment of an artificial anus near the normal site.—B. F. Kingsley.

The Technique of Lumbar Puncture.—The location for entering should fulfil three requirements: (1)

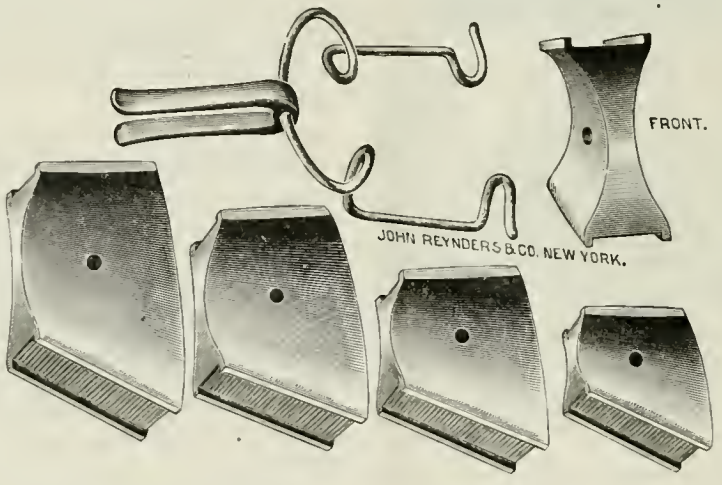
where the needle could find a ready entrance; (2) the tip should point in such a way as least likely to produce damage; (3) the fluid obtained should be rich in sediment. Any one of the three lower lumbar spaces should be chosen. At the lumbo-sacral space the fluid should be richer in sediment. The patient should assume the sitting position, but in the delirious, or comatose, there is greater difficulty in operating in this position. The upright position is generally confined to small children. An essential point to remember is that the greatest degree of flexion should be maintained; if the child is sitting it should be bent well forward; the operator should stand on the right side of the patient and bend over the body.—L. A. Connor.

New Instruments.

DESCRIPTION OF NEW INSTRUMENTS: (1) LIP RETRACTOR; (2) INTERDENTAL MOUTH PROPS.

By S. ORMOND GOLDAN, M.D.,
NEW YORK.

The lip retractor was devised to overcome a mechanical obstruction to breathing not infrequently met with when administering anæsthetics to old patients. This is due to atrophy of the alveoli and atony of the muscles about the cheek and lips. These subjects, in expiration, balloon the cheeks and lips, but do not effectually separate them; during inspiration the lips are drawn together, valve-like, without air entering the oral cavity.



The retractor is of two sizes and made of light-weight rigid wire, twisted into supports for the upper and lower lips and a lateral support united at the centre, which fits the cheek externally and internally at the angle of the lips, and permits the retractor to remain in place during the entire narcosis. Breathing is unimpaired, and the anæsthetic may be administered without any interference with the close adaptation of the face-piece of the inhaler.

Mouth Props. Certain types of patients develop during the administration of anæsthetics a respiratory obstruction due to abnormally small air passages, not discoverable before the administration of the anæsthetic. This is also frequently met with in mouth breathers. When ordinarily the patient is subjected to the mouth gag and barbarous tongue forceps, this is entirely avoided by slight separation of the lower jaws and the insertion of one of the smaller props; breathing continues uninterruptedly throughout the anæsthesia, the prop remaining in place.

The larger sizes for adults, and the smaller ones for children, are particularly useful in dental and oral operations. The props are made of four sizes, either hard-rubber or metal, and are so designed that a rubber band encircles the prop, making a rubber cushion over the serrated surfaces, upon which the teeth rest. The upper surface is horizontal, the lower oblique, conforming perfectly with the lower jaw when it is depressed. The narrowest vertical surface is introduced first and as far back as possible, with the oblique surface inferior. The props are united in pairs by narrow tape knotted on the opposite side of the perforation through the centre.

225 West Forty-fifth Street.

Medical Items.

School of Tropical Diseases for Germany. — A school of tropical diseases similar to those already in existence in London and Liverpool is about to be opened at Hamburg. Dr. Nocht, the port medical officer of Hamburg, has been visiting the English schools for the purpose of studying the work in each establishment, since the Hamburg school will work in co-operation with the two English schools. Dr. Nocht has had an interview with Mr. Chamberlain, the English colonial secretary, who is intensely interested in the subject. It is contended that once malaria is suppressed in West Africa the country will become a second India.

Mortality of Typhoid Fever in South Africa.— There has been much futile discussion, says *The London Practitioner*, as to the mortality of typhoid fever in South Africa, and statistics have been compiled from all available sources to show, according to the controversialist's point of view, that the death rate in Lord Roberts' army has been normal or that it has been excessive. Military statistics are to be distrusted in the matter of typhoid fever. The twenty-one per cent. of deaths admitted by Lord Roberts will doubtless, when the official report of the war comes to be written, be reduced to an infinitesimal fraction by dilution *secundum artem* with cases of "continued fever." Already the employment of his process has been foreshadowed by Bennett Burleigh in his account of an interview with Lord Roberts published in *The Daily Telegraph* of July 2d.

Poisons and Poisoners.—Italy was the sapient nurse of the finer arts of the poisoner. In the fifteenth, sixteenth, and seventeenth centuries professional poisoners were common in Italy and found a large sphere of practice. Poison was recognized by churchmen as a means of preferment, by statesmen as a useful political instrument, and even by governments as an engine of diplomacy. Poison was, in fact, the common means of getting rid not only of a dangerous enemy and an inconvenient rival, but of a troublesome husband or a wealthy relative who lagged too long "superfluous on the stage of life." The character of the Italan mind made it prefer the subtle instrument of poison to the grosser methods of murder practised by more barbarous races. It is largely its historical association with poison that gives the name of Borgia its sinister celebrity. In this particular respect more has been laid to the charge of the members of that unscrupulous family than the evidence fully justifies; nevertheless,

on ne prête qu'aux riches. But the poisoned gloves and flowers, which are said to have been instruments of death in their hands, are almost certainly mythical. Such legends, however, show the fear which the black art of the poisoner had bred in the public mind. The toxic agent chiefly used by professional poisoners in antiquity and in the Middle Ages was arsenic. This remained the poison most in favor up to the present century. The famous "aqua tofana" was a solution of arsenious acid in distilled cymbalaria water, to which was added some alcoholic preparation of cantharides. Arsenic from the poisoner's point of view has the advantage that the symptoms produced by it when skilfully administered are not very characteristic, and may easily simulate natural illness. Examples of this have been afforded by the history of several celebrated criminals of modern times. It was the poison most used by Madame de Brinvilliers, who said of it, "*Il n'en faut pas donner trop à la fois afin que l'on ne s'aperçoit pas, et que cela fût trop precipité.*" Being tasteless it was easily given in food and drink. But when the fear of poison got hold of men's minds this simple plan was difficult to carry out. Recourse was then had to such devices as poisoned shirts, slippers, gloves, etc., or the inside of the cup itself was coated with poison.—*Practitioner.*

The Antarctic Regions.—Dr. Frederick Cook, of Brooklyn, who has the unique distinction of being the only man who has been in both the Arctic and Antarctic regions, has just published a book relating his experiences. Dr. Cook was the surgeon and anthropologist of the Belgian Antarctic expedition which passed the season of 1898–99 in South-polar waters. The *Belgica*, the name of the ship in which he sailed, spent thirteen months frozen in the pack. *The Sun*, commenting on Dr. Cook's book, says: "The effects of the Antarctic night upon the health of the men were serious. They suffered from anæmia in a more severe form than Dr. Cook met in his Arctic experiences, or than is recorded in the literature of polar exploration. Of the eighteen men on shipboard one officer died and another barely escaped death. The men became pale, the heart action grew feeble, and the stomach and other organs were sluggish and refused to work. There was difficulty of respiration if the slightest exercise was taken. All these unfavorable conditions disappeared when the summer day fairly returned."

A Case of Mould Infection in Man.—Ophüls and Moffitt describe a mould parasite from the case of a farm laborer who died after an illness characterized by pleuritis and inflammatory swelling of the joints, with high temperature, cough, slight rigors, and profuse sweating. In the pus of various abscesses which were found after death, a number of protozoon-like bodies were identified which appeared to correspond with the description given by others of a species of sporozoon coccidioides immitis pyogenes. From pus containing these bodies, however, a mould parasite developed on artificial media after forty-eight hours' incubation. After three subcultures had been carried out, a rabbit was inoculated with the mould. The rabbit was killed three weeks after the inoculation, and a number of small white nodules were found in the lungs and kidneys. No mould mycelium was present in the nodules, but there were a number of the protozoon-like bodies which had been found in the original pus. The authors conclude, therefore, that these bodies are not protozoa at all but represent a stage in fructification of the mould parasite.—*Public Health.*

Railway Accidents.—According to the report of the Interstate Commission, the total number of casualties to persons on account of railway accidents during the year ending June 30, 1899, was 51,743. The aggregate number of persons killed as a result of railway accidents during the year was 7,123, and the number injured was 44,620. Of railway employees 2,210 were killed and 34,923 were injured in the course of the year. The number of passengers killed in the same period was 239, and the number injured was 3,442. Corresponding figures for the previous year were 221 killed and 2,945 injured. The total number of persons other than employees and passengers killed was 4,674; injured, 6,255. The total number of persons killed at highway crossings was 693; injured, 1,125. The number of persons killed at stations was 443; injured, 3,306. The summaries containing the ratio of casualties show that 1 out of every 420 employees was killed and 1 out of every 27 employees was injured. One passenger was killed for every 2,189,023 carried and 1 injured for every 151,998 carried.

Gender of Automobile.—The question of the gender of the word "automobile" has just come up for adjudication by the French Academy, and the "Immortals" have decided to make it masculine. Many French purists disagree with the Academy. Still it seems eminently proper to make the rattling combination of iron and fire or electricity masculine.—*Scientific American.*

A Tax for the Benefit of the Tuberculous.—The Paris correspondent of *The Lancet* says that at the Congress of Hygiene Dr. Phicque, physician in charge of the sanatorium in Agincourt, proposed the establishment of an additional tax upon alcohol, of which the profits should be applied to the expenses of the fight against tuberculosis. An additional penny (*décime*) to the present tax of 156 francs per hectolitre would bring in 25,000,000 francs per annum. The French duties were at present much lower than the American, 245 francs; the Dutch 252 francs, and, above all, the British 477 francs per hectolitre. The creation of the "tubercle duty" upon alcohol would, according to Dr. Phicque, be perfectly justifiable, for alcoholism is the principal cause of pulmonary phthisis. With the 25,000,000 francs which the duty would bring in, sanatoria could be built, and all the expenses, which are very high, of disinfecting unwholesome houses could be defrayed.

Physique of Chinese. — Commander Webster, U.S.N., says that in physical appearance the natives of China vary widely from extreme north to south. While our experience in the United States leads us to think that the race is small and undersized, a brief residence in the northern provinces of the empire will go far to dispel this impression. At Chefu, Taku, and Tien-Tsin one is struck by the stalwart appearance and height of the natives. At the first-named port large numbers of the men are six-footers, and among the boatmen of Chefu it is no uncommon thing to see a native over six feet in height weighing nearly or quite two hundred pounds. In the South, however, the average is more nearly accordant with the specimens we encounter as laundrymen, gardeners, and coolies generally in the United States. The cue or pigtail by which Chinamen have become so well known is the visible mark imposed by their Manchurian conquerors in 1644. Notwithstanding the length of years since the imposition of this mark of subjection, there are large numbers who resent the cue.—*Scientific American.*

The Antagonism of Diseases.—According to Hahnemann, his colleagues, when they happened to cure a patient, did so by introducing another and antagonistic disease—that is, by allopathy. This is now what is definitely aimed at in many cases, and it is interesting

to find that it was also definitely aimed at by our remote predecessors. Rufus of Ephesus, for example, a contemporary of Galen, has a chapter on the antagonism of diseases which is preserved in Oribasius, and which may be condensed as follows: "Fevers are catarrhs and spasmodic affections, and burn up morbid humors. Certain Africans use the goat's urine to provoke fevers, as did also the Greek physician, Evenor. Quartan ague will cure epilepsy and asthma, also obstinate leprous eruptions and fevers, which last also cure it. Chronic dysentery will cure epilepsy and vertigo. Hemorrhoids are good for melancholia and mania, epilepsy and vertigo, and protect against pleurisy, pneumonia, and acute fevers. Varicose veins act similarly, but less strongly. Therefore the cure of either piles or varix is not always safe." There may be some truth in the above, though we should now reduce the list, and it omits a notable case of supposed antagonism, viz., that between phthisis and mitral disease or emphysema. This was discovered at the Naples Congress on Tuberculosis by Drs. Fazio and Stefanile, who collected twenty cases of aortic and fifty-nine of mitral disease, only two of which were tuberculous, and thirty-five patients with emphysema, one of whom only was phthisical. They conclude that the antagonism of the two latter diseases to phthisis merits further consideration.—*Medical Magazine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 8, 1900:

		Cases.	Deaths.

The Air of Rooms.—Mr. Francis Jones, F.C.S., of the Manchester grammar school, England, has completed a most useful piece of research work on the effects of various methods of lighting and heating on the air of rooms. One of his principal results is that gas, either as a heating or lighting agent, should be used as little as possible if the air of the room is to be kept pure. Taking as the standard of purity an atmosphere containing not more than thirteen parts of carbonic acid in 10,000, the only combination for lighting and heating an ordinary room on an average winter day was found to be that of a coal fire and electric light. This did not raise the carbonic acid to more than 12 parts, whereas a coal-fire with gas speedily ran up the average to 27 parts. A gas cooking-stove, even though provided with a flue leading into the chimney, increased the carbonic acid up to 40 parts per 1,000, and while the burners on the top were in use up to 84 parts. What must the condition of the atmosphere be when, as is often the case, there is no flue? The humidity of the air is also reduced by gas fires. One noticeable point in the pamphlet deserves the attention of those who in carrying out the ordinary quantitative examination for carbonic acid take the most elaborate precautions against possible errors in experiment. Mr. Jones declares that he never quite succeeded in obtaining air free from moisture and carbon dioxide.—*Medical Magazine.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PHELPS OPERATION FOR HERNIA AND METHOD OF CLOSURE OF ABDOMINAL WOUNDS.[1]

BY A. M. PHELPS, A.M., M.D.,

NEW YORK,

PRESIDENT OF THE NEW YORK STATE MEDICAL SOCIETY; PRESIDENT OF THE AMERICAN ORTHOPÆDIC ASSOCIATION FOR 1894; MEMBER OF THE NEW YORK ACADEMY OF MEDICINE AND THE NEW YORK COUNTY MEDICAL SOCIETY; VISITING SURGEON TO THE NEW YORK CITY HOSPITAL; PROFESSOR OF ORTHOPÆDIC SURGERY AND VISITING ORTHOPÆDIC SURGEON TO THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL; PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, ETC.

IN 1892 I became thoroughly convinced that the reason why relapses occurred after operation for hernia, and why hernias so frequently followed abdominal operations, was because the scar tissue stretched after the operation. I was perfectly familiar with the fact that the profession had for more than a hundred years used silver wire in various surgical operations; that it had been used for wiring fractures, and had been introduced to the profession by J. Marion Sims more than forty years ago in gynæcological work, and by other operators. I also became convinced from my clinical observations that the reason why silver wire used by the method taught by the great masters frequently gave disturbances requiring its subsequent removal, was because it was improperly used.

These two propositions forced themselves upon my mind, and led to a very careful investigation, the results of which started important experimental work in the New York City Hospital in 1892 and 1893. The results of that work in hernia were reported to the New York Academy of Medicine in April, 1894, and published in the *New York State Medical Journal* in September of the same year. Subsequent to these dates, I have repeatedly offered to this same medical body, and also to the New York State Medical Society, communications upon the subject.

Since 1892, I have operated upon two hundred and sixteen cases of hernia; forty-six were relapsed Bassinis, and fifty-one from other operations, chiefly that of McBurney, and all abdominal wounds I have closed with silver wire, and fortified after a method which is original so far as I know, after looking up the literature upon the subject.

It is a well-known clinical fact that scar tissue will stretch, and it is immaterial whether the wound unites by primary union or not; a certain amount of scar tissue must be the result, and the stretching of this leads to the hernias following abdominal work. To obviate this, I introduce a continued suture of fine silver wire which becomes encysted, and remains so during the natural life of the patient. In extremely thin abdominal walls, in addition to this, a mattress of loops of silver wire is introduced over the transversalis fascia, and underneath all of the muscular coats of the abdominal walls. This wire becomes encysted in the granulation tissue, preventing subsequent stretching. So far as I know, silver wire has always been introduced into tissues as an interrupted suture, the fear being that it might cause disturbances and could be easily removed. If this wire is sewn into the tissue with continued suture, it always becomes encysted and causes no disturbance whatever.

Now, in hernia operations, I take advantage of this idea, and fortify the inguinal canal with a mattress of wire, stitching the muscular layers over it, entirely obliterating the inguinal canal, bringing the cord out underneath the skin, and cutting the aponeurosis of the muscles so as to prevent strangulation of the cord.

FIG. 1.—Mouth of the Sac after it has been Cut Away. A continued suture of wire closes it precisely as is done in any laparotomy. The cord is retracted with gauze.

Relapses in oblique hernia take place at the internal abdominal ring, or, in other forms of hernia, at the external. One of the very serious mistakes made by all operators is the ligation of the sac. Frequently—and I have observed it post mortem—after a ligation of the sac, retraction takes place of the peritoneum and transversalis fascia, leaving a large surface, varying from three-fourths of an inch to two inches in diameter, which is not covered by the fibrous tissue and natural support of the abdominal walls. Then, to obviate this accident, I cut off the sac and retract it from the operation precisely as I would from any other abdominal operation, stitching up the peritoneum and transversalis fascia with a continued suture of silver wire, as seen in Figs. 1, 2, 3, and 4. Over the transversalis fascia and peritoneum a mattress of fine silver wire is placed (Fig. 2), and the deep layer of muscles stitched over it with continued suture of silver wire. A small glass drainage tube is inserted down to the wire mattress for the purpose of drainage. If a large hernial opening is to be stopped,

[1] Read before the Surgical Section of the Thirteenth International Congress at Paris, August, 1900.

and there is very much attenuation of the muscular coats of the abdominal walls, a second mattress of wire is placed between the layers of muscles and a

Fig. 2.—Shows the stitching together of the deep layer of muscles from the spine of the pubis to one inch beyond the internal abdominal ring. The mattress of silver wire, the finest made, is looped or knotted and finally matted together and placed over the transversalis fascia, covering the entire inguinal canal to one inch external to the internal abdominal ring. It can be seen in the figure partially covered by the muscles which are being stitched over it. The cord is retracted with gauze. This is the second step of the operation.

superficial layer of muscles, together with the aponeurosis stitched over it (Fig. 2). The cord is brought out from the inguinal canal externally and inferior to the internal abdominal ring. A notch made by cutting with scissors in the aponeurosis of the muscles prevents strangulation, and the cord lies directly under the skin in its course to the scrotum (Fig. 3).

My paper, presented to the New York Academy of Medicine in 1894, giving the results of my work from 1892, was a preliminary one. Before taking up all of the steps herein enumerated, and a great many others which experience has demonstrated to me are entirely useless, for the reason that I did not wish to present to the profession an incomplete method of operating on hernias, I have deferred presenting anything on this subject until more mature observation and experience in hundreds of cases might verify any statement which I might make.

I am now prepared to urge the profession to adopt the operation which I here present for hernia in any form, and for the purpose of preventing relapses in any abdominal operation of any name or nature. The operations upon the relapsed Bassinis which I have performed are of very great interest, or should be, to the profession. The primary operations had been performed in our best hospitals, and also in private practice, by the best surgeons that the United States of America can furnish, and I predict that the day is not far distant when Bassini's operation, and all others except the one that I here propose, will be abandoned by every operator.

It is very important to the surgeon in private practice to know that he can state truthfully to his patient that he can operate, and guarantee that there will not be a relapse. The operation which I here propose places the surgeon exactly in that position. I know of no other operation for hernia that safeguards the operator against the possibilities of relapse. There is no more danger from the operation than from any other. There is no danger from any irritation of the wire. The mortality in my series of cases is *nil*, and the possibilities of relapse are nothing. For these reasons, if for no other, the method should commend itself to every operator. The method has been accepted by Professor Schede, of Bonn, Germany, and by other distinguished surgeons of that country. It has been accepted by many of the leading surgeons of the United States. And, speaking personally, I cannot too strongly urge the profession to adopt this procedure in preference to all others.

In my original article, I devoted much space to the treatment of the sac, believing this was one of the fertile sources of relapse in hernia, but I am now fully convinced that the sac should be dealt with by radical methods, and a hernia operation should be converted into a small laparotomy to secure the best possible chances of success. As a matter of fact, when we examine into the etiology of oblique inguinal hernia, we must become thoroughly convinced from the time of the descent of the testicle behind the kidney during fœtal life to its future repository in the scrotum, that, to a certain extent, the abdominal walls in this part of the anatomy must necesarily be weakened.

And then again, the distention which follows hernia still further absorbs the muscular and fibrous tissue, resulting in a great loss of substance. And the only way to secure a strong resisting point at this weakened portion of the abdominal walls is by reproducing a large amount of inflammatory material, and preventing its stretching by a material that will not absorb, and so elastic that it will bend with every motion of the body.

Silver wire answers this purpose. The use of catgut, silkworm gut, kangaroo tendon, or any other ma-

Fig. 3.—Superficial Layer of Muscles and Aponeurosis Stitched with a continued Suture of Wire. The cord is retracted and the aponeurosis notched.

terial which will be absorbed, defeats the very object at which we aim. The use of silk is positively contraindicated, on account of the dangers of infection. Silver wire, taken from pure carbolic acid, heated to a red heat with an alcohol lamp before its introduction into the wound, furnishes us a material which is thoroughly sterilized and cannot possibly produce irritation, and all the dangers of infection are avoided.

In two hundred and sixteen operations, I have had infection at the seat of the wire mattress sixteen times.

The question naturally arises in the mind of the operator: "What will you do when infection takes place in this mattress of wire? Will you remove it?"

FIG. 4.—Shows the wound closed finally with a continuous suture of catgut which includes only the skin

Most certainly not. Lay the wound open with a fine curette, curette out all of the infected portion, and fill the wound with pure carbolic acid, afterward wash it out with alcohol, which is a perfect antidote to the corrosive effects of carbolic acid, and allow the wound to heal by granulation. In every one of the cases so treated, not one single case has relapsed, and that portion of the abdominal walls is the strongest part.

Cases with sinuses have been discharged from the City Hospital by the incoming staff before the sinuses were closed. Such sinuses should have been opened and treated before they left the hospital. When the patients were admitted to other hospitals the surgeon

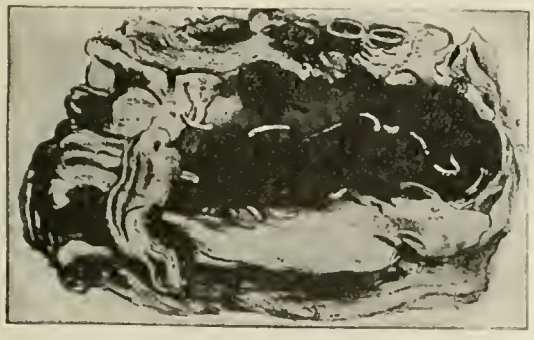

FIG. 5 is the entire inguinal canal removed from a patient who died two and one-half years after the operation for hernia, from a hysterectomy. It shows the wire perfectly encysted and the mass of new tissue held together with the wire, which prevented stretching. The inguinal canal was completely obliterated and was the thickest and strongest part of the abdominal walls. No inconvenience was ever felt from the wire by the patient.

has removed the wire instead of following the plan which I always resort to, mentioned above—leaving the wire in. The results in the infected cases are equally as good as in the non-infected.

Another application of this method of using silver wire is in large cranial wounds with much loss of bony structure, and also in the restoration of ruptured and lacerated muscles. The opening in the skull I close by stitching across it fine wire, including the aponeurosis and periosteum on the other side of the wound. The stitching in the second row is at right angles to the first across the wound; this forms a network which prevents the cicatricial tissue from contracting and making pressure upon the brain. This method also prevents hernia cerebri. In rupture of muscles or in loss of muscular tissue from injury, I stitch the muscle together with a continued suture, and when there is loss of muscular substance the wire is stretched across from end to end of the muscle, care being taken that the wire shall be in the centre of the muscle with no ends projecting when reproduction has taken place. Such muscles are as strong after reproduction as before the injury, and the scar tissue between the end of ruptured muscles—for instance, the quadriceps extensor femoris or the biceps flexor cubiti—will not stretch because the encysted wire will prevent it. There are many other instances in which wire can be used in our surgical procedures, and when introduced as I have already suggested it will never occasion disturbance. Suppuration is never produced by the wire unless the germs of infection are introduced with it; then when suppuration does occur it is always an accident which might have been avoided.

TO WHAT EXTENT DOES "RHEUMATIC AND GOUTY DIATHESIS" ENTER INTO TRAUMATIC JOINTS (SPRAINS AND BRUISES), SEPTIC AND GONORRHŒAL JOINTS, ACUTE ARTICULAR RHEUMATISM, NEUROPATHIC JOINTS, ARTHRITIS DEFORMANS (OSTEOID, RHEUMATOID), AS AN ETIOLOGICAL FACTOR? WHAT IS THE SCIENTIFIC BASIS FOR SUCH A TERM?[1]

By WILLIAM HENRY PORTER, M.D.,

PROFESSOR OF GENERAL MEDICINE AND PATHOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING PHYSICIAN AT THE NEW YORK POST-GRADUATE HOSPITAL, ETC.

OF the six subdivisions propounded for discussion under the common subject, "Diseases of the Joints Often Diagnosed as Rheumatic or Complicated with Rheumatism," the one given above was assigned to me by your committee. The question is composed of two distinct parts, the last of which calls for elucidation before the first can be logically considered.

Taking up first the question as to the scientific basis of the two terms "rheumatic" and "gouty diathesis" before we can decide their true position in connection with scientific medicine, we are at once forced to analyze the origin and literal meaning of these terms in the light of our present chemico-physiological and pathological knowledge. Take, for instance, the term "diathesis"; what is its true significance in relation to the chemistry of the human economy? For years the term "diathesis" has been used to indicate that something has been handed down from generation to generation, but what that something is has never been made clear to the science of medicine. Taking the literal meaning of the word diathesis from its Greek origin and applying it to the chemistry of the body, it must indicate simply and only that there is a tendency on the part of the animal economy to arrange the chemical phenomena of the system in certain and definite directions. This, however, does not justify the supposition that the individual is of necessity born to develop finally those symptoms recognized as constituting the conditions so long known under the terms

[1] Read before the Massachusetts Medical Society, Boston, June 13, 1900.

"gout" and "rheumatism." Therefore, the term "diathesis" as it is commonly applied has neither fact nor foundation to rest upon; for all the evidence at our disposal tends to prove that all diseased conditions, with the possible exception of syphilis, are acquired after birth. All are abnormal chemical states of the system which can be either fed into or fed out of the human race, so to speak. This, however, is assuming a very high and almost theoretically ideal position; nevertheless, it is one that can be practically accomplished, provided we can succeed in attaining the highest perfection in the hygienic and dietetic conditions influencing animal life. Thus we find, without going further into exhaustive details, that there is no real scientific basis for the term "diathesis" as it has been commonly used in the past. In fact, it would be better if this term were dropped entirely from medical literature.

In like manner, the terms "gout" and "rheumatism," when viewed from a purely scientific basis, are almost as meaningless as is diathesis. Naturally, with this statement before us, the first question that arises is, What is this so-called "gout" and "rheumatism" that we hear and talk so much about? Turning back to the derivation of the word "gout" we find that it comes from the Latin word *gutta*, meaning a drop. According to Dunglison's "Medical Dictionary": "Gout received its name from the French *goutte*, drop, because believed to be produced by a liquid which is distilled drop by drop on the diseased part. The name was first used about 1270." Hence, gout is the drop disease. This, however, gives no insight into the etiological factors entering into the production of the pathological conditions so long honored by this name. Nor does it give any suggestion as to the disturbances of the chemistry of the body, which ultimately bring about the pathological changes and symptoms so well recognized under the name "gout." We might possibly strain a point and say, in a similar manner to what has been said in the past, that the term "gout" was coined to indicate the dropping of the uric-acid radical into the protoplasmic structures of the various tissues of the body as the result of the final and vicarious oxidation of the proteid molecule in the tissues already made pathological by the prolonged disturbances in the chemical activities of the animal economy, vicarious oxidation being synonymous with the term "distillation" of the ancient writers, referred to in Dunglison's definition of the disease. Accepting this more modern interpretation, there might be some justification for considering the term "gout" as a word based upon our present scientific data. On the other hand, as this vicarious oxidation of the proteid molecule in the already pathological structures of the body is but one little factor in the great and complex chemical problem constituting the condition so long known by the name "gout," there is no logical reason for regarding the term as one resting upon a clearly elucidated and perfectly scientific basis. Furthermore, the condition known as gout, as commonly defined, is said to be one in which there is a production of uric acid in the blood, a condition, however, that never occurs, because chemistry forbids the separate presence of an active acid in a strongly alkaline solution without the formation of a salt of that acid; at least it cannot occur unless all chemical laws are suspended in connection with the blood. So far as my observation and researches have carried me, there is nothing to warrant the assumption that the well-known laws of chemistry have been suspended, so that uric acid exists as such in the blood and does not result in the formation of a salt. Furthermore, it can be asserted that uric acid does not exist in the blood, for the reason that the salts of uric acid have never been found there, as must have been the case had uric acid entered the blood stream.

The definition above mentioned further affirms that the phenomena recognized under the term "gout" are due to the non-elimination of the uric acid from the blood stream, and its subsequent discharge from the blood as uric acid into the protoplasm of the various structures of the body, by preference into the cartilage cells of certain joints. But this explanation does not tell why the acid refuses to attack the sodium and calcium compounds in the blood stream, but seizes upon them with intense activity as soon as it is discharged into the semi-solid protoplasmic structures. Thus we find that the whole theory of gout is developed largely without any reliable scientific foundation, at least so far as the name is concerned, and it also disregards, almost from beginning to end, the well-known and inflexible laws of chemistry, as we understand them today. The only indisputable fact in connection with the whole theory of gout, as it is commonly given, is the final deposition of the insoluble salts of calcium, together with some urate of sodium crystals, in the various structures of the body. Therefore, it can very justly be stated that there is no well-grounded scientific basis for the term "gouty diathesis."

When we come to the term "rheumatism" or "rheumatic diathesis," the mystery, so far as the derivation of the name is concerned, is greater even than is the case with gout. There is absolutely no scientific basis for the term. Yet under the term "rheumatism" is included a very great complexity of disturbed physiological phenomena. If we attempt to secure any information through the derivation of the word, we are led still farther away from any scientific basis for it. Taking its Greek origin, *ῥευματίσμος*, from *ῥεῦμα* or *ῥέω*, and translating it literally "rheumatism," would mean a fluxion, or flow, but of what or in what direction we are in total ignorance. The more modern definitions are almost as vague and uncertain as those based upon the old and long since discarded humoral theory of rheumatism. If there is no scientific basis for these terms, it is difficult to see how their relation to the topics under discussion can be elucidated or explained from a scientific standpoint. On the other hand, the natural inference is that both "rheumatism" and "gout" are, in a measure at least, connected with some of these joint affections under discussion. Before we can discuss any etiological relationship between "rheumatic" and "gouty" conditions and the joint affections enumerated, we must first have some fixed and definite conception of the chemico-pathological phenomena that are to be included under these terms. The weight of evidence, however, both chemico-physiological and clinical, points clearly to defective oxidation on the part of the system as the chief predisposing factor in bringing about these two dissimilar conditions.

In the majority of instances the chief cause for a suboxidation state of the system is the ingestion of more oxidizable food than there is oxygen absorbed through the lungs to reduce completely the proteid constituents to the normal end-products. In other instances, diminution in the food supply, together with that of a poor quality, may so deteriorate the nutritive activity of the system, that a pronounced anæmia is produced, thus cutting down the intaking capacity of the animal economy for oxygen to such an extent that there is not sufficient oxygen absorbed through the lungs to oxidize perfectly the little proteid that is taken in the limited supply of food. Hence, too little or too much food may act as determining factors in producing an imperfect oxidation of the proteid constituents. It matters little whether the proteid be derived from the vegetable or the animal kingdom. Its imperfect oxidation, and the toxic products developed in consequence of incomplete oxidation transmutation, are the factors which excite the symptoms.

Attributing these pathological conditions to a sub-

oxidation state of the system does not fully explain why in the one instance the result is "rheumatism" and in the other "gout." This was at one time attempted by assuming from the general clinical history that those individuals who partook freely of starches and saccharine substances developed "rheumatism," while those who lived largely upon an animal class of foods and used alcoholic beverages freely as a rule developed the condition called "gout." This was during the period in which lactic acid was supposed to be developed from the incomplete oxidation reduction of the saccharine elements, and when uric acid was supposed to be the product of an animal diet only. That both uric acid and lactic acid do result from the imperfect utilization of the proteid constituents derived from the vegetable as well as from the animal kingdom is a well-established fact. With this understanding of the oxidation problem it is easy to comprehend how both "rheumatism" and "gout" can be developed from an excessive diet of either vegetable or animal food. It does not explain fully, however, why a liberal vegetable diet is more likely to produce the condition called "rheumatism," and the liberal animal diet is more likely to produce the condition called "gout." At the same time it must be clear to every one who has observed many cases clinically that certain kinds of diet have a decided influence in determining the nature of the suboxidation processes. It should further be remembered that none of these incomplete end products found in the excreta is to be considered as constituting the disease any more than urea constitutes normal nutrition. They should be regarded only in the light of results, or indicators by which the different types of suboxidation can be recognized and differentiated.

The development of the so-called rheumatic condition cannot be explained as it was at one time by assuming that lactic acid is the chief etiological factor in producing the disease, and that this so-called lactic acid or rheumatic condition is due to the imperfect oxidation of the starches and sugar alone, while the gouty condition is due to imperfect oxidation of the proteid constituents. Assuming that such a condition is true from a chemical standpoint, it does not explain the development of the rheumatic condition so called in those who live almost exclusively upon an animal diet, in which there is no excess of the starch and sugar to undergo imperfect oxidation reduction. Therefore, such a theory is absolutely untenable both from the chemico-physiological and clinical data at our command. Hence, we are forced to the assumption that in the so-called lactic or rheumatic condition, as in the so-called uric-acid or gouty state of the system, all the toxic products found within the system and all the abnormal products found in the excreta are due to the imperfect oxidation reduction, or faulty isomeric transformation of the proteid constituents contained in the animal economy. This fact accepted, our theories can easily be made to fit all the clinical facts met with. Now, we can readily understand how it is that overindulgence in the starches and sugars is so prone to excite imperfect oxidation of the proteid constituents. The starches, sugars, and fats, all being easily and quickly oxidized into their complete end products, if taken in inordinate quantities will overtax the oxygenating capacity of the system, and there will not be left sufficient oxygen to complete the more difficult task of perfectly oxidizing the proteid constituents. In this manner they act as very potent factors in bringing about the imperfect oxidation of the proteid elements. Further than this, their oxidation being differently effected from that of the proteids, it is easy to understand how their excessive utilization may have a result upon the system different from that of an excessive use of the proteid constituents, thus, in a measure, explaining why, in the one instance, we are more likely to have "rheumatism," and in the other the "gouty" condition.

As there seems to be so much confusion in the minds of many in regard to the true position and meaning of these imperfect products of proteid oxidation, and especially in reference to the most common of all, namely, uric acid, it may not be unprofitable to enter a little more into the detail of the formation of uric acid and its significance in connection with health and diseased conditions. Uric acid is one of the substances by which nitrogen is eliminated normally from the system. It is an almost insoluble and very stable substance. It was first separated from human urine by Scheele in 1776. It is a dibasic acid, having two replaceable hydrogen atoms, one of which is easily substituted by sodium, forming an acid urate, or biurate, of sodium. Both of the replaceable hydrogen atoms can be substituted by sodium, but, so far as is known, only the acid salt is a product of the animal economy. This urate is relatively soluble. Uric acid is formed by the oxidation of the proteid molecule or its derivatives, and is a lower oxidation product than urea, in the same manner that urea is a lower oxidation product than ammonia and carbon dioxide and water, which are the final products of proteid oxidation, chemically speaking. Why urea is the final oxidation product in man instead of ammonia, carbon dioxide, and water has never been explained, further than to state that it is according to the original plan of nature.

It has been claimed by some that uric acid is not an oxidation product, and they base their claim on the fact that this acid and its salts are the normal and complete excrementitious products in birds, reptiles, etc., in which animals the oxidation powers are said to be exceedingly high. However, there is nothing to prove the capacity of birds, reptiles, etc., to take in oxygen, or of the blood to distribute this oxygen, and of their system to utilize it, and that it is sufficient to oxidize all the assimilated hydrocarbons and proteid compounds into their final and complete products. At any rate, to draw such an inference is begging the question. The chemical fact remains that their excreta, as compared with those of the higher order of animals, are products of a lower proteid oxidation, just as urea is lower than the final product ammonia. Why in the one species the chemico-physiological apparatus of the animal economy is so constructed that uric acid and its urates are the final excretory product, while in another it is urea, is just as mysterious and absolutely unfathomable as are the phenomena of life and death. In what follows I shall endeavor to show that in man the production of uric acid in quantities above the normal is due to a condition of suboxidation.

The two most prominent theories advanced to explain the genesis of uric acid in the system are: (1) That it is an oxidation product manufactured in the renal cells; (2) that it is made in some manner in the liver, spleen, etc., but chiefly in the liver. Minkowski,[1] Schröder,[2] Horbaczewski,[3] are among the more recent defenders of the latter theory, while Garrod[4] is generally credited with the former. The latter view is the one that has been accepted generally and on the following grounds: First, that uric acid is found in the blood; second, that in gout it is found in the tissues; third, that after extirpation of the kidneys uric acid continues to be formed; and, fourth, that at the height of digestion, when the liver and

[1] Minkowski: Arch. exp. Path. u. Pharmak., xxi.

[3] Horbaczewski: Monatshefte f. Chem., x., 624.
[4] Garrod: Lumleian Lectures. Lancet, vol. i., 1883.

spleen are most active, uric acid is most abundant in the urine. In this connection it may be remarked that in all the experiments which have been brought forward to sustain the theory that uric acid is formed outside the kidneys, or in the liver, there have been produced profound abnormal or pathological states of the system. Therefore they should be completely discarded from a physiological standard, as all deductions founded thereon are upon a purely pathological basis, and not normal.

The claim that is so commonly made that free uric acid is found in the blood is not tenable, as we have already seen; for, on coming into close relation with the alkali metals, salts of the same are immediately formed. Therefore, if this nitrogenous organic acid were in the blood, it would be in the form of a urate only, and, as already stated, such a salt has never been found in the blood. The statement that uric acid does exist in the blood is based upon Haycraft's[1] method for detecting uric acid, or upon others of a similar nature; as they all admit of a possibility of oxidizing the proteid elements, and thus producing uric acid in the process for detecting this compound, they cannot be relied upon as proving the existence of uric acid in the blood. Some have claimed to obtain good results from this method. On the other hand, Salkowski[2] regards the process as of little value even in solutions known to contain uric acid, as the composition of the silver urate formed is not constant; this opinion is further supported by Gossage.[3]

On the other hand, it has been, and is still, distinctly affirmed that free uric acid and its biurate salts do exist in the blood; and the method called upon to explain the possible presence, in some form, of uric acid in the blood is by the so-called "quadurate" (quadriurate) theory. The following statement made by Roberts,[4] the author of this theory, in his description of his method for obtaining the quadriurate, tends to prove that the quadriurate—if it really has a chemical existence—is an accidental rather than a constant product, for he says: "To obtain a product of uniform composition by this process requires a somewhat nice adjustment of the reaction. If the quantity of alkaline carbonate added be faint, the precipitate, on cooling, is apt to be contaminated with free uric acid. On the other hand, if the alkaline carbonate be added too freely, and the resulting alkalescence be excessive, the precipitate is apt to be contaminated with biurate. These risks are greatly minimized by using the alkaline acetates instead of the alkaline carbonates." From this it appears that Roberts failed to obtain the quadriurate with the regular uniformity necessary to establish his theory; in fact, the nice adjustment of the reagents required for the precipitation of the quadriurate might lead one to believe that with this test the precipitate was a mixture of biurate and uric acid in quantities to satisfy the theoretic demands for the quadriurate.

In Watts'[5] "Dictionary of Chemistry" is the following: "NaHO + ½ Aq. (dried at 100) = crystalline powder. Occurs as an amorphous urinary deposit." This statement, together with the fact that the alleged quadriurate is an amorphous deposit and very unstable, makes it appear highly probable that the biurate is still the form of urate most commonly found in the urine. It is not necessary to find a more soluble form of urate than the acid urate, for it is well known that the disodic monohydrogen phosphate,[6] which is often present in the urine in abundance, will hold large quantities of uric acid in solution. It is also known that the uric acid in the urine, and in the absence of any newly added chemical agent, steadily attacks the disodic monohydrogen phosphate, so that when the acid phosphate, which will not hold the uric acid in solution, has replaced the neutral phosphate, the uric acid is precipitated—all of which occurs naturally and without adding anything to the urine as is required for the demonstration of the presence of the quadriurate according to Roberts' theory. The one occurs naturally, and the other requires very nicely adjusted reagents for its demonstration. This method, which may be called the natural one, of precipitating uric acid in urine which apparently contains no excess of the acid, can be artificially quickened by a very simple procedure. This is best done by filling a test-tube with urine and bringing the upper stratum to the boiling-point; then adding a drop or two of a four-per-cent. solution of acetic acid and setting the tube aside in a cool place. At the end of a few hours, if there is an abnormal amount of uric acid contained in the sample and held in solution, as already described, the heat and the acetic acid will excite chemical action between the uric acid and the disodic monohydrogen phosphate, with a rapid formation of the monosodic dihydrogen phosphate, thus destroying the solvent power of the urine for the uric acid. Now the uric acid will rapidly be crystallized out, and the amount so formed, when collected on a filter and weighed, will give the exact percentage of uric acid in excess of the normal amount. In this manner and in a few hours the exact quantity of uric acid can be estimated. When the amount of uric acid is normal in the urine, no precipitation of the acid can be effected by this method. It then requires the use of a considerable quantity of one of the stronger mineral acids, sufficient to decompose the normal urates, and thus set free the uric acid otherwise held in combination with the sodium, before its presence is demonstrated.

The quadriurate, as has been said, is a very unstable compound, and one that is easily broken up by washing with water. This being the case, its decomposition and the subsequent demonstration of the uric acid and the biurate in the blood should be easily accomplished. No mention is made, however, of finding the so-called quadriurate in the blood, but it is introduced artificially into the blood serum and synovia; and from this it has been claimed that it can exist in the blood, but failure to demonstrate its presence directly in the normal blood stream is not a proof that it does not exist in that medium. The production of the quadriurate in the system necessitates first the production of uric acid. So far, in connection with the quadriurate theory, we are in total ignorance as to the point where the uric acid is manufactured, also as to where it attacks the sodium compounds to form the theoretical salt, and where the latter finally gains access to the blood. Until these doubtful points have been cleared up satisfactorily, the quadriurate theory is one grand speculative problem which does not explain the facts as developed by clinical observation. Unless our theories can be made of practical value in the study and management of the case at the bedside, they are of no real value.

From all the preceding, it can be justly deduced that uric acid and its urates have not as yet been clearly demonstrated in the normal blood stream. That uric acid and its urates are found in the tissues in pathological conditions is true. This, however, does not necessitate the assumption that uric acid or its urates existed in the blood stream in defiance of all the known laws of chemistry. But it does demand the hypothesis that, as a result of a faulty nutrition, there is developed an imperfect and abnormal trans-

mutation of the proteid compounds; that, as a result, these substances are oxidized at an abnormal position, instead of in the renal cells as normally occurs; that when this is the case there is a sudden production of uric acid and the formation of urates in the protoplasmic masses, and that when this happens all the symptoms are those which indicate a profound irritation and an increased chemical activity. Thus, by assuming a vicarious production of uric acid, a theory which holds true in many other abnormal and pathological conditions in the body, the presence of uric acid, or rather the urates, in the tissues is explained by simple chemical phenomena, and without deviating from any well-defined law of chemistry. All this can be done without predicating that uric acid or its urates are present in the blood.

The pathological condition which is produced by extirpation of the kidneys will admit of the formation of uric acid by the vicarious oxidation of the proteid substances in the protoplasm of cells other than those of the renal gland, upon the same principle as given in the foregoing example.

Upon the theory that uric acid is due to a deficiency in the quantity of oxygen reaching the body as a whole, and the renal cells in particular, the manufacture of uric acid by the kidneys should normally be greatest during digestion and least during the interval; for, during digestion, the carbohydrates, fats, and proteids are being introduced into the circulation in large quantities. The two former are rapidly oxidized, the one in the liver and the other in the lungs, tending to use up the oxygen supply, so that a deficient amount of oxygen reaches the kidneys and a less perfect transmutation of the proteid in the renal cells is the result, while the output of uric acid is augmented. Thus, a normal physiological phenomenon, which is called upon to explain the production of uric acid in the liver instead of the renal glands, when viewed in this light, makes it appear quite plain that no such deduction is justified. It rather strengthens the theory which points to the renal cell as the true source of the uric-acid production, except in pathological states of the system, when it can be made at abnormal points by the vicarious action of the protoplasmic masses.

This theory of uric-acid production by the oxidation of the proteid substances in the protoplasm of the renal cells is by far more logical, is best sustained by all the points in evidence, and fits most accurately all the known facts and conditions. This formation of uric acid is one method for the elimination of nitrogen from the system. It is absolutely necessary to have this acid produced at this particular point and poured into the uriniferous tubules; for by its action upon the disodic monohydrogen phosphate in the uriniferous tubules the monosodic dihydrogen phosphate is produced, and the production of this acid phosphate of sodium is absolutely necessary to hold in solution the otherwise insoluble phosphate of calcium, thus preventing the formation of this form of calculi in the urinary passages.

The theory that the uric acid is produced in the renal cells in the manner described above is further substantiated by the steady presence of this acid or the urates in urine, and by their absence from the blood.

When uric acid is herein contrasted with urea as a suboxidation product, it is not meant to intimate that uric acid is the direct antecedent of urea. On the contrary, it is one of the complete end products of proteid oxidation so far as the animal economy is concerned, just as much as urea, carbon dioxide, and water are final products. Chemically, less oxygen has been utilized to produce this particular form of compound than is required to produce urea and the other higher oxidation products. Physiologically, when produced in excess, it is a suboxidation product, for it is found that the output of uric acid is always augmented by anything which interferes with the utilization of the full amount of oxygen by the system, as compared with the quantity of food-stuffs absorbed. A prolonged high tension of the arterial system, under the influence of digitalis, for instance, causes the blood to be driven through the capillary blood-vessels so rapidly that sufficient oxygen cannot be taken up from the blood and utilized for the complete transmutation of the proteid elements of the food. As a result, suboxidation occurs, and the manufacture and output of uric acid by the renal cells are increased. The same is true with every condition of the system which produces a prolonged high tension of the vascular system and a rapid pulse rate. When the intaking capacity of the lungs for oxygen is diminished by mechanical defects in the heart, or by pneumonia, pleurisy, emphysema, etc., the oxidation of the proteid substances falls to an abnormally low degree, the excretion of urea decreases and that of uric acid increases, the latter often to a marked degree. When the carbohydrates or fats are taken in excessive quantities, and especially the former, the oxygenating capacity of the system is exceeded, the more difficult task of oxidizing the proteid elements is imperfectly performed, suboxidation ensues, and, as a result, uric acid increases in the urine, while the urea output decreases. When an excessive amount of the proteid substance is taken, either alone or in combination with the carbohydrates and fats, the oxygenating capacity of the system is exceeded in a similar manner, and the proteids are imperfectly oxidized as before.

When the uric acid rises above the normal, it is simply a symptom found in the urine, which indicates an imperfect state of proteid oxidation and a general condition of malnutrition. This suboxidation may be, in a measure, caused by many different conditions, acting singly or in combination, causes which may arise either in the nervous, digestive, circulatory, or in the respiratory system. In every instance there is more or less profound impairment in the glandular activity and nutritive tone throughout the whole system. In some instances one organ or tissue will suffer more than another, and thus the symptomatic manifestations are varied and irregular in their development. When the renal cells temporarily cease to act, thus failing to produce uric acid, the associated defective state of nutrition results in many instances in the various masses of protoplasm throughout the body, which are now in an abnormal physiological state, assuming an abnormal or vicarious action. In this manner the proteid substances are oxidized into uric acid in the cells of the tissues, with the immediate production of the urate of sodium. This abnormal oxidation may occur in any protoplasmic mass which is in this state of malnutrition, but it is most commonly met with in the cartilage cells of the metatarso-phalangeal articulation of the great toe. It does, however, occur in other parts of the body and in other tissues than the cartilaginous structures. This development of uric acid in the cartilage cells, or at other points of the body, results in its immediate precipitation at such points as a urate of sodium. This abnormal deposit acts as an intense chemical irritant, and excites a local inflammatory process by which a fibro-plastic exudate is thrown around this foreign body until the urates are finally incapsulated, and gradually all the local symptoms subside.

The problem has further been very much simplified by the fact, now generally recognized, that all the non-nitrogenous food products, such as starch, sugar, and fats, are directly oxidized into their end products, carbon dioxide and water, and that they do not yield any

toxic by-products to the system. Therefore we are left to deal chiefly with proteid constituents as the etiological factors in the production of these toxic and suboxidation conditions of the system. This much established, we still have no clear and complete explanation for the different degrees and forms of suboxidation processes which constitute the various diseases, such as so-called rheumatism, so-called gout, etc.

Strenuous attempts have been made in this bacteriological age to associate a specific germ with all pathological problems, and in many instances this has apparently been successfully accomplished. Still, the declaration of the presence of a specific germ as the causative factor in the production of disease does not explain in full the special and characteristic features of the pathological lesions found, or the symptoms by which the different diseases are characterized. Working along these lines, a considerable number of observers profess to have found a specific germ as the causative factor in the production of so-called rheumatic conditions of the system. Among this number may be mentioned von Schueller,[1] Buss,[2] Brunner,[3] Buday,[4] Petrone,[5] Hlava,[6] Tizzoni,[7] Goldscheider,[8] Loeffler,[9] Boulloche,[10] Mantle,[11] P. Guttmann,[12] Fleischhauer,[13] Waibel,[14] Bouchard,[15] Sahli,[16] Lucatello,[17] Leyden,[18] Singer,[19] Chvostek,[20] Humphrey,[21] and Young.[22] All of these observers have given more or less attention to this subject. Buss states that he considers it highly probable that acute articular rheumatism, so-called, is in many, perhaps in the majority, of cases, caused by attenuated pyogenic micro-organisms, among which he includes the Friedländer pneumo-bacillus and the diplococcus of Fränkel-Weichselbaum. Sahli[23] cultivated streptococci from the blood and contents of affected joints in cases of so-called acute articular rheumatism. Singer[24] made bacteriological examinations in seventeen cases of so-called articular rheumatism, and secured positive results in sixteen instances. In ten cases he found staphylococcus albus, in one staphylococcus aureus, in three streptococci, in two staphylococcus albus and streptococci. He further argued from his observations that the constancy of the occurrence of the micro-organisms in the urine, and the fact that the number of the colonies obtained diminished in number as the symptoms improved, were sufficient evidence for considering a coccus infection as the exciting cause of the disease. Chvostek, on the other hand, made repeated observations in twelve cases of so-called rheumatic affections of the joints. In one of these cases he found the diplococcus ureæ; in another, in which the urine was not drawn with a catheter, staphylococcus albus; and in a third, large cocci, which have not yet been described, but which probably, according to Chvostek, are derived from the urethra. In this connection it should be remembered that Krause[1] has shown that bacteria are often excreted in the urine during infectious diseases, which have no connection whatever with the particular infection from which the patient is suffering, and which must not, therefore, be regarded as the exciting cause of the disease. Among these bacteria the staphylococcus albus plays an important part. And this is the form of micro-organism that has most frequently been described in connection with these rheumatic conditions. Krause further says that these bacteria are no longer found in the urine when all the signs of disease have vanished, simply, as he argues, because the conditions of the system necessary for their growth have been removed.

Chvostek[2] extended his examinations and made examinations of the blood, urine, and articular fluids, in cases of so-called acute and chronic articular rheumatism as well as in cases of other infectious diseases in which an acute swelling of the joint takes place. The results which he obtained from his examination of the articular fluids were negative in all his cases, except in the changes in the joints that arose directly in the course of a sepsis or a gonorrhœa. Chvostek sought further to discover whether the bacteria which are present in the blood entered the joints during the life of the patient, and, if so, the conditions necessary for their transit through the wall of the blood-vessels. In this connection it may be mentioned that his experiments on animals showed that certain alterations in the nutritive composition of the vascular wall must be produced before the passage of the micro-organism could be effected. He also demonstrated, to his own satisfaction, that the construction of the synovial membranes and that of their contained blood-vessels resisted to a high degree this nutritive change that makes possible the passage of the germs, thus rendering it very difficult for the micro-organisms to pass through the walls of the blood-vessels and gain access to the joints. This is not the case, however, with the vascular walls of the kidneys. Hence the bacteria, if they appear at all in the joints, will do so at a much later period than they are excreted by the kidneys.

That micro-organisms have been found in the urine, and in some instances in the blood, and in the fluid accumulations in the joints, and in various structures of the body, in connection with the varying conditions which have been described under the common term rheumatism, cannot be denied. We may even go further and state that the prevailing organism, when described at all, is most frequently of the coccus type.

From the great diversity of results obtained, and from the fact that no one form of micro-organism is found with any degree of regularity in connection with these so-called rheumatic conditions, the consensus of opinion is, that the pathological conditions and symptoms classed as rheumatic are not to be attributed to the direct and intrinsic bacterial invasion of the structures of the body, as is the case in connection with some of the well-known and undisputed microbic diseases. Nevertheless, it is reasonable to suppose that in conjunction with over-feeding and with under-feeding, and the consequent suboxidation state of the system, the action of the micro-organism and the toxic products that are developed as a direct result of their presence in the alimentary canal are largely responsible for the different forms and degrees of suboxidation included under the terms gout, rheumatism, etc. The micro-organism in all these instances acts by its presence in the alimentary canal, and by its disturbing influence upon the digestive process, and not by its inherent presence within the intrinsic structures of the system.

To understand this proposition thoroughly, it must be remembered that the presence of certain kinds of bacterial life is, in all probability, absolutely essential to a perfect performance of the digestive function. In this connection it must also be remembered that only a few years ago Nuttall and Thierfelder,[1] in a series of experiments in which they used young guinea-pigs, apparently proved that the alimentary canal could be kept free from all bacterial influences, and a perfect nutrition at the same time be maintained. In opposition to this is the fact that in almost all instances the alimentary tract at all times contains various micro-organisms. Added to this are the more recent experiments of Dr. M. Schottelius.[2] Dr. Schottelius' series of experiments was carried out in a manner similar to those of Nuttall and Thierfelder, but instead of selecting the guinea-pig, hens and their eggs were utilized for the experimental work. Two sets of eggs were taken, one in which the surface of the eggs was made absolutely free from bacteria by washing with a strong solution of bichloride of mercury, the remaining set remaining contaminated by micro-organisms. The first, so far as their exterior is concerned, will be called for convenience sterilized eggs, while the other batch will be designated as non-sterile eggs. The former were introduced into a sterile incubator, while the others were not. When the chickens were hatched, those from the sterilized incubator were carefully fed upon sterilized food, while those of the control experiment were given ordinary food. The fæces were carefully examined in both instances. In the first set, or the so-called sterile chickens, the fæces were found to be absolutely free from all forms of bacterial life, while the reverse was found to be the case in the control experiment. At the end of a certain period of time the non-sterile batch of chickens were found to have gained in weight much more rapidly than the sterile batch. The gain was two hundred and fifty per cent. greater in those in which the bacteria gained access to the alimentary tract. Further than this, all of the so-called sterile chickens died within three weeks after they were hatched, while the control chickens lived on as usual. Thus it would seem to be clearly proved that for the most perfect working of the digestive function in the alimentary tract, and also for assimilation, the presence of certain kinds and amounts of bacterial life and their chemical products in the alimentary canal are absolutely essential.

To determine which form of bacterial life is essential for the maintenance of a perfect physiological state will require a long series of experiments, in which the composition of the food is accurately determined before being ingested. At the same time the excreta, representing the utilization of the foodstuffs and tissue waste, must be accurately studied. Then the various kinds of micro-organisms at work in the contents of the alimentary tract must be determined through a study of the bacterial life found in the fæces. With this there must also be associated an isolation of the various kinds of bacteria found in the contents of the alimentary canal in connection with the condition recognized ordinarily as the normal state. Then the action of the bacteria should be carefully studied on the normal sterilized and non-sterilized foodstuffs outside the body; and this must be done with the bacteria singly and in combination. Their action should also be studied upon the food in the presence of the various digestive ferments. When all this has been accomplished, a very fair knowledge of the action of germs in the digestive process in the normal state will be secured. Then, in a similar manner, their action upon the digestive process could be studied in connection with the conditions designated as intestinal indigestion, and also in connection with all the pathological processes which appear, in a large measure at least, to take their origin in an imperfect digestion and assimilation, and in which an incomplete oxidation is a leading feature of the disease, as occurs in the so-called gout, rheumatism, Bright's disease, diabetes, etc.

While all this desirable information is not as yet at our command, there is a sufficient evidence at hand to warrant the assertion that the varying degrees and kinds of suboxidation met with, such, for instance, as the so-called gout and rheumatism and a host of other conditions, are the result of some special kind of micro-organism acting in the alimentary canal; or they may be the result of two or more varieties acting together; or may it not be that the absence of certain kinds of bacterial life is the determining factor in the production of the disease process? In either instance it may be assumed that abnormal or toxic products are produced in the alimentary canal, which, when introduced into the circulation with the foodstuffs, act as the direct and determining factor in establishing the special degree or form of suboxidation that we know by these time-honored names, "gout," "rheumatism," etc. By assuming the development of a variety of toxic products it easily explains the great variety in the clinical picture as witnessed under the so-called rheumatic condition.

This line of argument is sustained, so far as the symptoms are concerned, by the fact that with the introduction of certain chemical compounds into the system definite symptoms follow, as when morphine, strychnine, atropine, pilocarpine, etc., are introduced. Why morphine, strychnine, atropine, pilocarpine, etc., are always followed by a pretty uniform train of symptoms depending upon the special one used has never been absolutely explained. Yet no one attempts to deny the fact. In a similar manner it is reasonable to suppose that the symptoms of disease are the result of the introduction into or development within the system of definite chemical compounds; that these chemical products either emanate directly from the micro-organism or are produced from the proteid constituents in which the bacteria grow, by the action of the bacteria upon the proteid molecule. This latter view appears to be the more probable, taking all things into consideration. The modification of the physiological phenomena by the introduction of the varying toxic products can also be made to explain the varying pathological conditions met with; just the same as the introduction of chemical compounds can be made to modify pathological phenomena, and thereby enable the system to be brought back into a more nearly physiological condition. In all these suboxidation diseases the action of the bacteria is on the proteid constituents as they exist in the chyme rather than upon those which exist as integral parts of the body.

Thus we find that the two great predisposing factors in the development of so-called gout and rheumatism are the prolonged intake of a larger amount of nutritive pabulum than the system can perfectly oxidize, or conditions that so reduce the oxygenating capacity of the animal economy that the small amount of food taken cannot be perfectly oxidized. Added to this, as the exciting and determining factors in the production of the special type encountered, are the action of the bacteria on the proteids in the alimentary canal and the formation and absorption into the system of toxic products in conjunction with the food products absorbed. These two factors acting together determine the form of the suboxidation, the nature of the pathological lesions, the character of the symptoms, and the abnormal and by-products that are found in the excreta. It is largely by the latter that we are enabled to differentiate accurately between the different forms

[1] Nuttall and Thierfelder: Zeits. f. phys. Chem., xxi., p. 109.
[2] M. Schottelius: Arch. f. Hygiene, xxxi., p. 240.

of these suboxidation conditions that afflict humanity. In conjunction with the two predisposing factors and the exciting factor in the production of these suboxidation conditions there are a few other things that must not be overlooked, as they often exert a decided influence in determining the final result. They are the varying changes in the temperature, hygienic surroundings, nervous disturbances, etc., for they are all very important factors and help to disturb the perfect working of the glandular system. Just how the *modus operandi* of this bacterial factor working in the alimentary canal can best be absolutely determined is the question that is still pressing for an answer from the physiological chemists. Until it has been fully solved, the absolute etiology of these suboxidation processes under discussion, so-called gout and rheumatism cannot be absolutely elucidated except in theory. But even in the absence of this much-desired complete verification, this explanation, as here given, adheres more closely to all the facts thus far known to modern science than any explanation previously advanced.

With this conception of the chemical conditions that are at work within the system, when affected with so-called gout and rheumatism, the etiological relation of these conditions, if any exists, can be applied to the various diseases that are under discussion. It is nevertheless difficult to comprehend how false feeding, the action of the micro-organisms in the alimentary canal, and a toxic infection of the system therefrom, can in any manner be looked upon as a primary etiological factor in the production of a traumatism to a joint, a sprain or a bruise. Therefore, it must be asserted in the very beginning that there is no direct primary etiological relationship between the so-called rheumatic condition of the system and traumatic lesions of the joints. On the other hand, it is equally true that the abnormal chemical condition of the system which produces that state of the animal economy classed as "rheumatism" and "gout," will assert itself, and modify the whole course of the pathological problem in connection with a traumatism. This does not warrant the supposition, however, that the so-called rheumatic state of the system in any manner acts as a primary etiological factor in producing the traumatism of the joint structures. Penetrating a little more deeply into this intricate problem, we find that the products absorbed from the alimentary canal, and which, if retained in the system, are the determining factors in producing the special type of suboxidation that excites the lesions and symptoms classed as rheumatic, will influence the pathological changes following a traumatic injury to the joint. This is assuming, however, that there have been false habits of feeding, micro-organisms at work in the alimentary canal, absorption of toxic products into the system, and that, in consequence thereof, the animal economy has been or is on the verge of the suboxidation state called rheumatism prior to the receipt of the injury. In other words, after a mechanical or macroscopic traumatism to the joint structures, the nutrition in the injured parts, in one who is suffering from this characteristic chemical state of suboxidation of the system, which just precedes and makes possible the so-called rheumatic condition, will undergo changes different from those occurring in a more normal state of the system. When this term toxic product is used in connection with the diseases under discussion, it is understood that one of two conditions exists: either the system contains one or more by-products which have resulted from an incomplete oxidation reduction of the proteid elements, or the system contains proteid molecules, which, instead of pursuing their normal isomeric transformation course, have been deflected therefrom. When this latter occurs, the proteid molecule is so changed, isomerically, that it becomes toxic in its character, yet it still remains an unoxidized proteid body. This irregular isomeric transformation of the proteid bodies and their change into a toxic form easily explains the toxicity of the system. It further shows the difficulty, if not the absolute impossibility, of detecting the presence of these toxic proteid bodies as they circulate in the blood and lymph stream. In whatever manner produced, the toxic product which, prior to the injury, was eliminated from the system without exciting any active symptoms, will often aid in intensifying the pathological changes and symptoms resulting directly from the traumatism. Lesions and symptoms which would not have developed in the absence of the traumatism are produced by virtue of the presence of the suboxidation and toxic condition of the system called "rheumatic." On the other hand, they would not have occurred in the presence of the traumatism in a system perfectly free from so-called gouty and rheumatic conditions. In instances of this character, the so-called gouty and rheumatic states of the system can be looked upon as etiological factors in the production of some of the pathological changes and symptoms which follow direct traumatisms to the joint structures. They are, however, always secondary and never primary.

This relationship of the so-called gouty and rheumatic condition of the system should always be taken into consideration in connection with every traumatism that implicates the joints. If such a state of the system is found to be present, it must be given due consideration in the general management of the case; otherwise recovery will be greatly retarded.

In one instance that came under my observation, a severe wrench to one of the great toes had occurred in a gentleman past fifty years of age. This injury was followed by all the characteristic symptoms common to an ordinary attack of so-called subacute or chronic gout. So long as the case was treated as one of simple traumatism, which was the method pursued before he came under my care, there was no pronounced or permanent improvement. From the moment the condition was regarded as being primarily traumatic in its origin, and, in a large measure, secondarily kept in motion by the gouty suboxidation condition of the system which preceded the traumatism, and that the treatment was modified in accordance with this latter view, improvement was steady, and a permanent cure was speedily effected. Here the traumatism precipitated the so-called gouty attack, if I may so state it, and the only line of treatment that could be effectual was one directed toward removing the suboxidation state of the system. This is only one of many cases that could be cited in illustration of this principle. The same holds true in connection with the so-called rheumatic conditions. On the other hand, we frequently meet with instances in which slight fractures running into the joint and dislocations of the carpal and tarsal bones are diagnosticated as so-called rheumatic affections. Thus we find that there may be a commingling of the two conditions, both acting as etiological factors, even in connection with simple traumatic injuries of the joints. Therefore, each and every case examined must be carefully analyzed by itself, and due consideration given to the traumatism and to the possible influence that a previously existing suboxidation state of the system may at the time exert in the production of the lesions and symptoms. When this is systematically done, treatment will be more scientifically applied and the restoration of the involved joint to its normal functional activity be more speedily effected.

With the septic and gonorrhœal affections of the joints, all that has been said as to the relation of so-called gouty and rheumatic conditions of the system to

a traumatism can similarly be applied to these two diseases. The so-called gouty and rheumatic states of the system are in no sense primary etiological factors in the production of a septic or so-called gonorrhœal joint. Both, however, may play a secondary part in determining the nature of the lesions and the character of the symptoms as in the simple traumatic affections of the joints; but their influence will not be so well marked as it is in the former instance. This is especially true in connection with a septic joint, in which the intensity of the suppurative process and its symptoms mask all those of a minor character, and also because death usually occurs early in the disease. The same may be said in connection with so-called gonorrhœal infections of the joints; for it is still an open question whether the acute joint symptoms developed during the course of the gonorrhœa, or following as sequelæ, are not due to a direct septic infection instead of a gonococcus invasion of the joint.[1] With so-called gonorrhœal rheumatism, which develops many months after the acute gonorrhœal attack, the suboxidation state and the toxic involvement of the system through the alimentary canal are in all probability more largely responsible for the pathological changes and symptoms than is the gonorrhœal infection. Thus the so-called rheumatic condition may play a large part in the development of the lesions and symptoms in so-called gonorrhœal affections of the joints; but it is always a secondary and never a primary cause. Still, in the management of all these cases it must be carefully considered and the treatment directed accordingly if the best results are to be attained.

When we come to the consideration of those conditions commonly classed as acute articular rheumatism, we for the first time reach a point in which the errors in diet, the action of bacteria in the alimentary canal, and the absorption or the development of the toxic products directly traceable to their presence, act when they are introduced into the system as the direct etiological factors in determining the special type of suboxidation. In this manner we can further look upon the suboxidation and toxic invasion of the system from the alimentary canal as the direct and exciting cause of the so-called gouty and rheumatic affections. The great variety of toxic products which can be produced in this manner in the alimentary canal and that can be developed within the system, as well as those absorbed from the alimentary tract, can be made to explain the varying degrees and types of suboxidation encountered. They can also be made to explain all the different forms and types of so-called rheumatic affections that are encountered clinically. This theory of the production of these lesions is well supported by that of Weigert[2] in his explanation of the various kinds and types of renal lesions that are known to exist. As yet, however, we are not sufficiently familiar with the micro-organisms and the toxic products to trace fully the *modus operandi* from the point of origin of the etiological factor to the final result. If, as seems quite probable, many of the toxic products are simply isomeric forms of the normal proteid molecule, it will be, as before stated, a very difficult matter to trace, isolate, and identify them. At the same time, from the data at our command, it seems reasonable to assume that continued errors in diet, the action of various kinds of micro-organisms in the alimentary canal, and the production of an almost endless variety of these toxic products can easily be made to explain the many forms and types of the so-called rheumatism, even from the slightest myalgia to the most extensive destruction of the joint structures. Even the so-called neuropathic joint affections can be elucidated upon this theory of a disturbance of the nutritive functions of the animal economy as they can in no other way. When one kind of toxic product affects the system, it, like some of the well-known drugs already mentioned, will influence the chemistry of the body in its special manner, and a certain definite train of lesions and symptoms will follow. The introduction of still other kinds will produce their special results, and an almost endless variety of examples might be mentioned. In the one instance the abnormal and toxic condition may result in a simple congestion only of the intermuscular planes with an undue pressure upon the nerve endings distributed to that particular part. Then we have the condition called muscular rheumatism. In another instance the abnormal and toxic condition, by virtue of a difference in the toxic product, will implicate the central or the peripheral nervous system and give rise to that class of cases which are known as neurotic and in which there is no very pronounced joint lesions. In still others the toxic elements will cause a more profound disturbance of the peripheral nervous mechanism, and thereby the action of the so-called trophic centres will be so profoundly disturbed that actual and pronounced destructive changes in the joint structures are produced, such as are found in Charcot's disease. The more common lesions, however, that occur as the result of this special type of suboxidation and toxic infection of the system classed as rheumatism, is one in which the vascular areas in and around the joints become congested, and are followed by a pronounced œdematous swelling of the soft structures in and around the joints affected. In all these cases it is the lowered nutritive activities and the action of the toxic products within the system, acting either upon the central or the peripheral nervous system, that cause the disturbance in the vascular and nutritive supply to the parts affected, and thus give rise to the anatomical changes and symptoms. In the vast majority of instances the injury to the structures involved in the so-called rheumatism is not sufficiently great to excite the phenomena characteristic of a true inflammatory process. Hence, with the removal of the cause and an improvement in the general as well as in the local nutrition, there is perfect restoration of the implicated joints to their normal state. In a few instances the primary injury from the toxic infection may be sufficiently great to excite a truly inflammatory process with all the changes characteristic of inflammation. In all these cases there is a tendency to more or less permanent damage to the structures in and around the joints involved. The amount and permanency of the damage to the joint will depend entirely upon the intensity of the primary injury and the duration of the actual inflammatory process.

The most extensive damage to the joints, however, is met with in those cases which are not inflammatory, but in which there is a long-continued general suboxidation state of the system together with its peculiar type of toxic infection. In these instances the continual augmented vascular supply to one area with a defective supply to another adjacent zone, but in both instances of material poor in quality and also toxic in its nature, causes a very irregular distribution of the nutritive pabulum with which to carry on the functions in and around the joints. So great and varied is this abnormal distribution of the nutritive pabulum, that almost all grades of new formations are met with in and around the joints. These vary from simple swellings consisting of atrophied fibrillated connective tissue infiltrated with a watery exudate into its meshes, to well-defined enlargements composed of dense fibrillated connective tissue almost as firm and well developed as the normal tendon tissue. These new formations are located chiefly in the ligamentous structures and around the ends of the bones at the point of the

[1] Young: Welch's Festschrift, p. 677–707, 1900.
[2] Weigert: Volkmann's Sammlung klinischer Vorträge, 1879, Nos. 162, 163.

attachment of the ligaments and tendons. This newly formed tissue in some cases is infiltrated with the insoluble salts of calcium and the urates, but it differs from the so-called gouty deposits in position rather than in kind. In the latter the salts are deposited by preference in the cells of the cartilage structures, while in the condition under consideration it is outside the joints and in the newly formed tissue.

In some rare instances there may be developed both a carious condition and the formation of new bone in and around the joint. These two latter conditions are very rare and always suggest the possibility of a syphilitic infection as an accessory etiological factor.

In all but this latter class this complex chemical suboxidation problem, with its associated toxic condition of the system which has for so many years been included under the so-called rheumatic condition, can be looked upon as the direct etiological factor in producing the lesions and symptoms of so-called acute articular rheumatism in all its varied forms, also the neuropathic joints, and some of the forms of arthritis deformans. This is especially so in all cases in which the joints become enlarged and distorted by the undue and irregular position of newly formed connective tissue.

In the osteoid types and in those cases in which a certain amount of caries occurs, it is highly probable that other etiological factors must be taken into consideration in explaining the loss of bone and the development of new bone. As already mentioned, it is highly probable that syphilis plays a decided part in producing graver changes, as it is well known that syphilis causes a decided tendency on the part of the system to bring about a carious state of the bone and a tendency to the formation of new bone.

This method of explaining the phenomena that occur in connection with the condition of the system so long known under the names "gout" and "rheumatism" places us in a much better position to prevent their development, and to displace them from the system when they have developed. It further shows in which of the diseases under discussion the "gouty" and "rheumatic" condition of the system acts as a direct etiological factor, and also in which its influence is only of a secondary nature.

PRIMARY CARCINOMA OF THE PAROVARIUM.

By B. S. TALMEY, M.D.,

NEW YORK.

For the pathologist, says Doran, the parovarium should be of great interest, as it plays such a prominent part in the pathology of cystic tumors of the broad ligaments. The vertical tubes of the parovarium have a tendency to develop solid growths. When they commence in the ovary they first appear in the tissue of the hilum, where rudiments of the Wolffian body exist. For the better understanding of the epithelial structures of the urogenital organs, I think it would not be amiss to review the embryonic development of these organs.

The urinary secretion is effected throughout the animal kingdom by three systems, the pronephros or head-kidney, mesonephros or primitive kidney, or Wolffian body, or "Urniere," and metanephros or true kidney. The pronephros must be regarded as the phylogenetically oldest part, since only traces of it are found in the human embryo. Here in the earlier stages of embryonic development the Wolffian body is the organ for the urinary secretion. The Wolffian body appears as two longitudinal protuberances on either side of the mesentery, along the spinal column, the ducts running alongside the abdominal aorta. The transverse excretory tubules or nephridia open into these pronephric ducts. Nephridia and ducts are lined by a high cylindrical epithelium. Very soon a small longitudinal ridge of the genital fold appears on the ventral side of the Wolffian body with the free surface toward the cœlom or body cavity. The Mullerian duct, the primitive female duct, arises from the mesothelium of the Wolffian body and lies close alongside of the Wolffian duct on its medial side. At the caudal end of the abdomen both the Wolffian and the Mullerian ducts open into the cloaca or hind end of the alimentary tract. The metanephros or true kidney appears first as an epithelial or renal evagination of the Wolffian duct on its dorsal side near its opening into the intestinal canal (cloaca). This bud grows forward on the dorsal side of the Wolffian body and becomes a long narrow tube (ureter), while the blind end changes into the kidney. The Wolffian body is now replaced in its function by the true kidney and

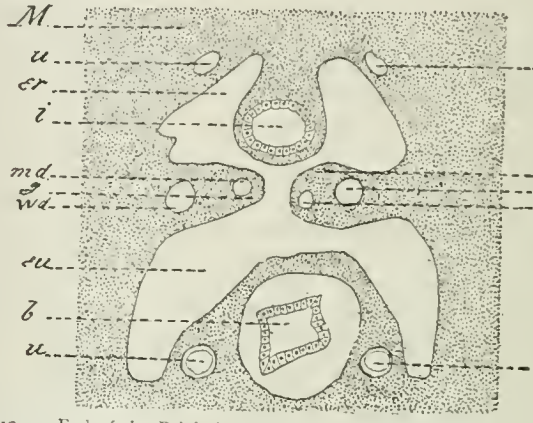

Fig. 1.—End of the Pelvis in the Height of the Bladder. Embryo three weeks old. *M*, Mesoderm; *u*, ureter; *er*, excavatio recto-uterina; *i*, intestine; *md*, Mullerian duct; *wd*, Wolffian duct; *g*, genital fold; *eu*, excavatio utero-vesicalis; *b*, bladder.

enters into special relation with the sexual organs. The genital folds are transformed into the indifferent genital glands and appear as two protuberances into the cœlom. In the female sex the genital glands or ovaries soon become bean-shaped with a free surface on the one side, the other being attached by the mesovarium, the later ligamentum latum. While the development of the ovaries is thus going on, the Mullerian ducts unite at the caudal end into the vagina and uterus, the upper blind ends diverge and form the Fallopian tubes. The Wolffian tubules and ducts lying between the Fallopian tubes and ovaries degenerate. The relics of the tubules, lined by a 16 μ high cylindrical epithelium, are called parovarium. While the epithelial elements of the ovary, the genital epithelium, "Keimepithel," as well as the follicular epithelium are cubical, the epithelium of the parovarium is a high cylindrical one (compare Figs. 1–4).

Epithelial tumors, even larger ones, embracing the ovary, parovarium, and ligamentum latum show, therefore, their origin by the shape of their epithelium. The erroneous conception of the possibility of a metaplasia of flattened epithelium into columnar is scarcely shared nowadays by any earnest observer. Columnar epithelial tumors of the adnexa, not starting from the tube, must therefore by necessity arise from the remains of the Wolffian body. This thought especially led me to declare the tumors in our case as of parovarian origin. The specimen to be described came from a woman, forty-three years of age, who died in June, 1899, after having been operated upon for a cancer of the pylorus several weeks previously. The autopsy was performed in the pathological institute of the University of Zurich. The following are the notes made of the autopsy of the genital organs:

Bladder empty; its mucous membrane pale and smooth. Vagina wide and smooth. Introitus externus of the cervix fissured. Uterus of the size of a

small apple, its muscles firm, mucosa without particular alteration. Left ovary changed into a tumor of the size of an apple. On the cut surface yellow and gray transparent nodules are noticed. Peritoneum intact. Right ovarian tumor of the size of a fist. The cut surface shows a partly opaque and partly transparent yellow appearance. Numerous minute cysts varying in size, with clear bright yellow contents,

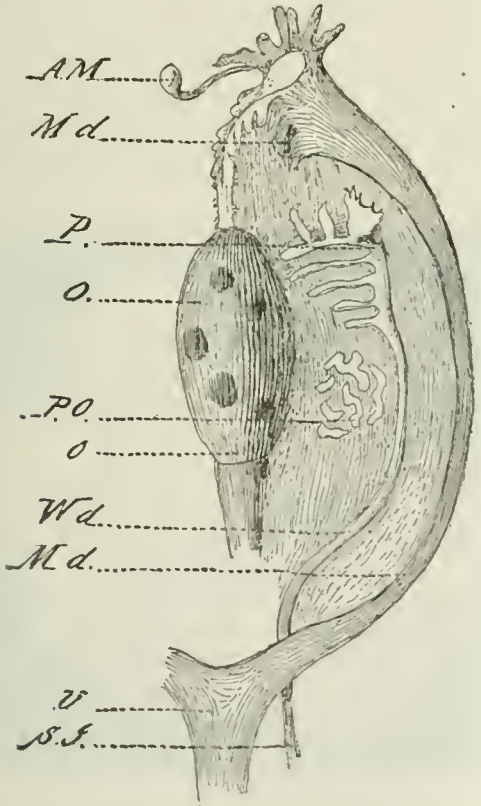

FIG. 3.—*AM*, Appendix vesiculo-Morgagni; *Md*, Mullerian duct; *P*, par-ovarian tubules; *O*, ovary; *PO*, par-oophoron; *Wd*, Wolffian duct; *u*, uterus; *SI*, Gartner's duct.

are seen on the surface. In the rectum nothing noteworthy. No implication of the floor of the pelvis.

Clinical diagnosis: Carcinoma pylori.

Pathological diagnosis: Peritonitis fibrinosa universalis perforativa, carcinoma ovarii.

The next day Professor Ribbert handed me the internal genital tract for the microscopical examination.

Uterus, vagina, bladder, peri- and parametrium are without any changes. A careful examination, particularly of the parametrium, showed nothing pathological. I failed to discover any enlargement of the lymphatic glands. The Fallopian tube runs alongside the upper boundary of the left tumor. The fimbriated extremity is somewhat enlarged. The fimbriæ are well developed. About 4 cm. beneath the tube a small oval outgrowth, measuring 3 cm. long and 2 cm. wide, projects from the main tumor by a small pedicle. This polypus-like appendix shows in its interior a circular flattened nodule of 1 cm. diameter. At the right larger tumor the Fallopian tube is not quite so distinctly limited as on the left side. A great many fimbriæ are here also preserved. Three to four centimetres below the Fallopian tube a polypus similar to that on the left side is attached to the main tumor by a broad, short pedicle. In its interior a similar nodule

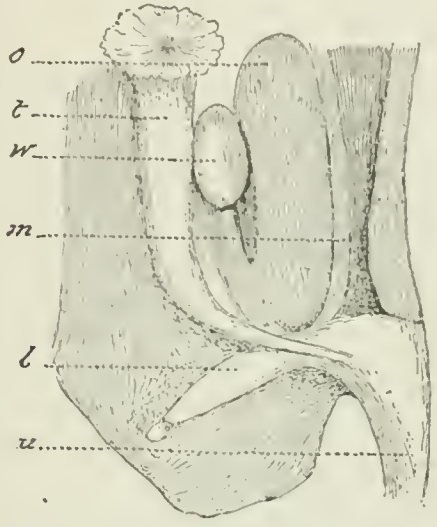

FIG. 4.—*o*, Ovary; *t*, Fallopian tube; *w*, Wolffian body; *m*, mesovarium; *l*, ligamentum teres uteri; *u*, uterus. (After Kollmann.)

to that on the left side is found. Both tumors were fixed in Zenker's fluid, hardened in alcohol, cut partly in paraffin, partly in celloidin, stained with hæmatonin Van Gieson and hæmatonin-eosin, and mounted in Canada balsam. The left tumor was first examined.

The microscopic examination showed the main mass of the growth to be composed of various irregular spaces lined with a single layer of high cylindrical epithelium within a richly cellular stroma. The lumina are oval or spherical and have a glandular aspect. They are sometimes occluded with broken-down epithelium. The cylindrical cells lie in a regular row, with the oval-shaped nuclei at the base. The protoplasm toward the lumen is three to four times longer than the nucleus. The contents of some lumina have a cystic appearance. At other points of the tumor the meshes are very small, containing only two to five single epithelial cells in regular rows and appearing to be on the point of forming an alveole, though I failed to find any cells in the state of mitosis. Sometimes single epithelial bodies are found in the midst of the stroma, and then the cylindrical character of the cell is not easily determined. The stroma contains numerous enlarged vessels with thickened walls and oval-shaped nuclei. Solid nests of epithelial cells are not rare, and even these cells are cylindrical in shape. Often nucleolated nuclei are observed. Some epithelial cells show at the top distinct vacuoles.

Examining under the microscope sections of the above-mentioned appendix, I found normal ovarian tissue with well-formed Graafian follicles lined with a

cubical epithelium. The stroma of the ovary has the normal amount of vessels. Cellular infiltration is nowhere to be seen, but there is a distinct increase of the fixed connective-tissue cells. At the border of the above-mentioned nodule within the ovary the mutually intergrowing of the connective-tissue and epithelial

FIG. 5.—Cut through the Left Cancer. *a*, Stroma; *b*, alveoles lined with a single layer of epithelial cells; *c*, cell nests; *d*, broken-down epithelium within the alveoles.

cells can be noticed. Single epithelial cells are surrounded by connective tissue. A little farther the epithelial cells become very numerous, and the tissue gives the appearance of being infiltrated by epithelial cells. They are now often lying in a regular row, are cylindrical in shape, and begin to assume a glandular appearance. Soon the meshes become larger and are lined with columnar epithelium. They are not, though, round or oval as in the larger tumor, and appear more like enlarged lymphatic spaces. The epithelial cells are not so high as in the main tumor, and where they are lying single the nucleus is not distinctly recognizable. The hilum appears normal. Old corpora lutea are noticed. Often the epithelial cells show a distinct degeneration, being more homogeneous and having lost their nuclei.

In the right tumor the conditions are similar. The tumor has an adenomatous structure, and can be classed among those growths which have been often called cylindrical epithelioma or malignant adenoma. The alveoles are of irregular size and lined with a high columnar epithelium. The larger alveoles contain a cystic mass, the smaller appear empty. Some epithelial cells are found in semilunar rows. Here and there solid epithelial nests are found. The tumor is sharply limited toward the ovarian tissue. The ovary contains some Graafian vesicles and corpora lutea, and resembles in every respect normal ovarian tissue.

The microscopical examination corroborates the assumption that the appendices represented the preserved ovaries. The invasion of the ovarian tissue by the cancerous process has already begun. But the partly preserved ovaries show that the tumor is not of ovarian origin. The intact hilum, as well as the high cylindrical epithelium of the alveoles, shows its parovarian origin. For granting even the correctness of the former generally accepted view of columnar epithelial cells being able to change into flattened epithelium, it is hard to understand how and why cubical and flattened epithelium should first change into the higher organized columnar epithelium, when already doomed to destruction. The metaplastic theory, as well as the assumption of a primary penetration of epithelial cells into the surrounding tissue, presupposes a change of the cells, for which we have no reason. However, we often see that various external or internal irritations cause a proliferation of connective tissue. The favorite organs for the cancer, on the other hand, are also those which are often exposed to such irritations. Hence Ribbert's theory ascribes the histogenesis of cancers to a primary proliferation of the connective tissue, which, penetrating between the epithelial cells, separates them from their continuity and encloses a variable number of them. The isolated cells, separated from their organic connection, continue their normal proliferating tendency within the connective tissue, dislodging and supplanting the latter and giving rise to a cancerous growth. They do not change their character, and less so do they alter their shape. This theory of Ribbert became a subject of debate. His most conspicuous opponent, Hauser, ascribes the growth and spreading of the primary cancer to a continual ingrowing of the proliferating epithelial cells into the connective tissue. The passing downward of single or rows of epithelial cells into the changed stroma is due to the faculty of the cancerous cells to perform amœboid movements. But the question remains the same, how a primary columnar-celled cancer could originate in an organ possessing normally only cuboidal epithelium. Now the main mass of our tumor is situated between the ovaries and the Fallopian tubes, where normally the pronephric relics are found, that in an early embryonic stage are lined with a cylindrical epithelium. Our tumors are, therefore, certainly of parovarian origin.

That these growths are metastases of the carcinoma pylori is scarcely to be thought of. The formerly widely accepted view, that cancerous cells could drop down from the stomach into the pelvis and continue their proliferation in the broad ligaments, is not shared nowadays by any earnest observer. The cancerous cells could, therefore, reach the broad ligaments only by the way of the lymphatics or blood-vessels. But it is scarcely probable that the cells on their long way from the pylorus to the pelvis would pass all the lymphatic glands without causing any metastasis anywhere, as in the liver and the easily affected mesenteric glands. If the cells had passed the vena porta, they would surely have left some changes in the liver. There is no plausible reason why the cancerous cells should just settle in the broad ligaments. In what relation does the epithelium of the pylorus stand with that of the parovarium or ovary? The shape of the epithelial cells in our case is also against the assump-

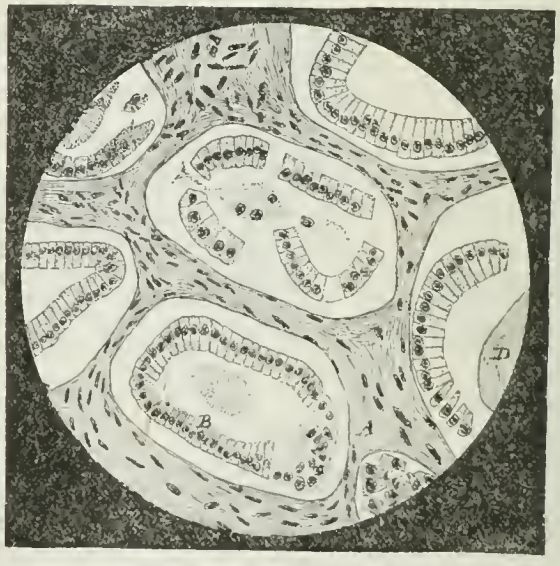

FIG. 6.—Portion of Fig. 5 more highly magnified.

tion of our tumors to be metastases of the carcinoma pylori. If Ribbert's account of the origin of cancers be correct—and I fail as yet to find any better theory—there is no possibility of epithelial cells changing their character, and the structure of the metastasis must be the same as that of the primary cancer. The cylindrical cancers of the pylorus are generally solid, true

cancers, the alveoles being filled with epithelial cells. In our case the alveoles are lined by a single layer of high columnar epithelium. The tumor is the true adeno-carcinoma as described by Ziegler, and it is improbable that a primary simple cancer will set up a metastasis of an adeno-carcinoma.

I am therefore led to the conclusion that the right parovarian growth is certainly a primary cancer. As to the left growth it is difficult to decide. The path by the lymphatics could be excluded, since the parametrium is in no way affected. There is no direct path across the uterus from one parovarium to the other. I would, therefore, rather incline to the belief that both tumors are two independent growths excited alike locally by a lower vitality and called into existence by a morbid substance existing throughout the body. Similarly Williams, in accord with Sir James Paget, declares in a case of his the cancers of both thighs to be independent of one another. Other writers also have observed multiple primary cancers in the same person. Mandry saw two cases, one of two primary cancers of both thighs, and the other of the external part of both ears. Johannowsky saw two cases of carcinoma ovarii bilaterale. Volkmann describes primary cancers of both thighs. Bruns affirms the existence of deposits of cancerous masses on two or more remote points of the body in one and the same person, which lie beyond the anatomical reach of the primary cancer, so that the younger growth could not have arisen from the primary tumor by a structural continuity of the cancerous masses. Hutchinson describes a case of two separate growths of epithelial cancer developed almost simultaneously on the opposite sides of the tongue. Bucher in describing two cases of primary cancers of the stomach and intestines says: "With our present knowledge we are not justified in assuming another path for the metastasis of tumors than by continued proliferation of the cell-elements to the other points." Billroth answers the question, whether in a given case the multiple cancers are primary or secondary, by demanding that, (1) the cancers should have a different anatomical structure; (2) that one cancer could not be derived histologically from the epithelium of the primary growth; and (3) that every cancer should set up its own metastasis. Of these three requirements the third is the least important, as we often see single primary cancers that do not set up any metastases. The other two conditions are given in the present case. We are therefore justified in assuming in our case a primary carcinoma of both parovaria.

A few words will now suffice to show how any connective-tissue proliferation in the broad ligaments could give rise to cancerous growths. The old authors have long given to the connective tissue an important part in the origin of cancers. Thiersch is of the opinion that any weakening change of the connective tissue enables the naturally energetic epithelial cells to penetrate into the deeper layers. Waldeyer also believes that epithelial remains, when enclosed in connective tissue and thus disturbed in their natural growth and function, often begin to proliferate in an abnormal way, and give rise to cancerous growths. Klebs demands as the characteristic features of the cancer a metastasis of the epithelial cells within the connective tissue at the outset. Boll finds also at first proliferation of the connective-tissue cells, which then give rise to the formation of embryonic vascular germ tissue. The resulting struggle for mastery between the connective tissue and the epithelium leads to an invasion of one another's territory, *i.e.*, to a cancerous growth. Recently, as above mentioned, Ribbert claims as the main cause for the origin of a cancer always the proliferation of the connective tissue elements resulting in a separation of the epithelial cells from their organic coherence and their implantation within the connective tissue. At the beginning of the cancerous proliferation a distinct boundary line of the two tissues cannot always be made out; instead a gradual transition of epithelium into connective tissue is always observed. It gives one the impression of the epithelium and connective tissue rushing pell-mell into the combat—no arrangement of cells of the former, rather small groups or even single cells. The isolated cells are not inert, however. The isolation of the epithelial cells once accomplished, they begin to proliferate within the connective tissue and form the alveoles, the epithelium growing in the line of the least resistance. The malignant metastasis of *a priori* benign growth (*e.g.*, adenoma strumæ) furnishes us the best proof for Ribbert's contention, that cells in other respects unchanged, once separated from their organic union, continue their proliferating tendencies in other organs under more favorable conditions and give rise to malignant growths. Ribbert has since completed his theory of the origin of flattened epithelial cancers from columnar epithelial growths. The increased proliferation of the connective tissue causes a kind of amputation of the lower ends of the glands. These separated ends do not always undergo cystic degeneration, but following the natural tendency of normal glands they penetrate incessantly into the deeper layers. In short, Ribbert attributes the origin of growths to an intra- or extra-uterine separation of the tissue-germs from their organic union. The isolated cell aggregations, withdrawn from the influence of their organic continuity, continue to increase on their own account and lead to atypical growths.

In our case there was from the start a natural metastasis of epithelial cells within a connective tissue. The relics of the Wolffian body are parts of an embryonic organ which has lost its function, and which in the female is doomed to degeneration. Now Zahan's experiment shows that non-embryonic tissue grafted from one animal upon another becomes encapsulated and inert, while embryonic tissue continues to proliferate. In our case the metastatic cells were of embryonic origin. Leopold says: "If a superfluous or foreign heap of cells occurs within another tissue, homologous or not, this cell heap, in accordance with its embryonic nature, has the faculty to increase enormously, needing only an increased blood supply, as is found in the human body during puberty or menstruation." Ribbert says: "Every mechanical stretching and every hyperæmia of the tissue which causes an increase in size of an organ, and in that way a separation of the individual parts of the tissue from one another, can also effect an abnormal proliferation." In our case we have a natural metastasis of embryonic epithelial cells in the connective tissue of the broad ligaments, that are certainly often exposed to natural changes of the blood supply and to various chronic irritations. If by any cause the tissue of the broad ligament undergoes modification, then all the conditions for the development of a cancer are present. The slumbering embryonic cells are again awakened to a new existence, and a tumor is the result.

Parovarian tumors are, therefore, not so rare. If all the so-called ovarian tumors were systematically examined under the microscope, a great part of them would certainly be found to be of parovarian origin.

SIMPLE FRACTURE OF THE SHAFT OF THE FEMUR, WITH REPORT OF TWO CASES OF DELAYED UNION.[1]

By WILLIAM H. SHIPPS, M.D.,
BORDENTOWN, N. J.

The successful treatment of fractures of the bony framework not only embraces union of the broken fragments, but restoration of function as well, and only when the two conditions are realized can it be said that we have achieved a perfect result.

Even under the most favorable circumstances, insuring the exercise of the highest skill, this is not always possible, and the results thus attained, while not so satisfactory either to patient or surgeon, in no sense militate against the skill or watchfulness of the latter, but in a majority of cases are due to causes over which he has no control. Fortunately the cases are rare in which, if the proper skill and care are exercised, the results are entirely unsatisfactory.

Apparently there is nothing specially brilliant in the setting of a broken bone or conducting the case to a successful issue. If we obtain satisfactory results, well and good; nothing else is tolerated by our professional brethren, while the laity at large look upon the healing of a broken bone as an everyday occurrence for which the surgeon is entitled to no special commendation, and, as a rule, he neither gets nor expects it. Once in a while, however, the results are not just what he had hoped for, and he is then not infrequently cheered by the kindly criticisms of his brethren in the profession, especially by that member who has been uniformly successful in every case he was called to treat. We all have met this personage—I know I have—and have seen specimens of his handiwork, too.

I well remember when years ago a student of medicine attending the lectures of that skilful surgeon and prince of clinicians, D. Hayes Agnew, hearing him lecture upon the subject of fractures in general. "Gentlemen," he said, "no class of cases coming under your notice in after-life will give you more anxiety or at times call for the exercise of greater judgment and skill than the diagnosis and treatment of fractured bones, and especially when they involve the neighborhood of the joints." "With all my experience," he added, "I to this day never approach a fracture of the elbow joint without realizing I am dealing with a grave injury, the outcome of which I cannot with certainty predict." When a surgeon of Agnew's attainments gives utterance to sentiments such as these, who will justify the indifference with which the general practitioner sometimes approaches this class of injuries?

And now just a word upon the medico-legal aspect of the subject. This always annoying complication may never have appealed to you, but it is likely to thrust itself upon you when least expected: consequently it is not amiss to devote to it brief consideration.

As before stated, notwithstanding our best efforts, occasionally deformity or more or less loss of function is the unpleasant sequela of injuries of the kind to which we allude, and too often the surgeon in charge is unjustly held responsible. It behooves us, then, as physicians and surgeons to exercise the greatest charity in our criticisms of these untoward results.

Unfortunately the tendency is to take advantage of our brother's misfortune, if such it be, and not infrequently by look or word furnish the pretext for a legal action that may be productive of untold evil to our medical associate. I have made it a point for years when requested to pass upon the treatment of a fractured bone, to avoid all semblance of unfavorable criticism even when it would seem circumstances justified it.

Years ago a noted surgeon said: "It has been my invariable rule to discourage in the most emphatic manner possible any criticisms reflecting upon the skill of a professional brother." Only recently he added: "A man came to my office with a decided limp, the result of a fractured thigh that had solidly healed, but with marked deformity and shortening. Divining that his purpose was merely to obtain an expression from me as to the treatment of the case, I proceeded to examine the limb carefully; which accomplished, I said to him: 'You should be very grateful at making so good a recovery.' As a result he left my office, disappointed with the verdict perhaps, but certainly with a very different feeling toward his attending physician than he had previously entertained."

I would that all of us exercised the same charity; were this the rule malpractice suits would be rarely heard of. Probably nine such cases out of ten owe their origin to the dishonesty of the patient, a dishonorable or thoughtless action of some member of our profession, and the cupidity of a shyster lawyer. These constitute the trinity that have to do with most of the cases that find their way into our courts seeking fictitious damages.

I will say to the younger men here present, watch your fracture cases most carefully. In most instances it is better far to call in some medical friend to assist at the first dressing; he will not only be of great assistance at the time, but may be of even greater service later on. The fracture cases I am most wary of, and in which I almost invariably call in outside aid, are those in the transient guests, who are with you today but away perhaps to-morrow, then to pass into the hands of some other surgeon or physician, who, in case of any untoward result following, is quite likely to attribute the same solely to the treatment instituted at the first dressing. But all this is a digression, a pardonable one I trust, from the subject proper of this paper, delayed union in fracture of the shaft of the femur.

In private practice probably not more than three per cent. of all fractures we are called to treat will be fractures of the femur. Of 1,712 cases of fracture treated in the Pennsylvania Hospital, 256 or fifteen per cent. were fractures of the femur. Of 51,938 cases treated in the London Hospital, covering a period of twenty-five years, 3,243, or more than six per cent., were fractures of the thigh. Edward Martin, of Philadelphia, in an article published in *The Therapeutic Gazette* for May, 1900, gives some exceedingly interesting statistics upon the subject of fractures of the femur, and from the results following treatment of the same draws conclusions for the most part not at variance with those of Holthouse, of London, Hamilton, Buck, and Manley, of New York, and Agnew, of Philadelphia, and calculated to make those of us in private practice who achieve good results triumphant, and somewhat comforted when we are less successful.

To quote from Martin's paper: "In the hope of determining with some degree of accuracy the ultimate prognosis of simple fracture of the shaft of the femur when treated by skilful surgeons and in accordance

[1] Read before the Burlington County Medical Society, June 19, 1900.

with generally approved methods, I have had a list made from the leading hospitals of the city, comprising all the cases treated in the wards of these institutions from 1890 to 1899. An effort was then made to find each patient in the list and to determine by direct examination the seat of his fracture, the method of treatment, the period of total disability, the period of partial disability, the amount of shortening or other deformity, and the amount of ultimate crippling."

Out of a list of several hundred, one hundred careful observations were made. Of the 100 cases, 45 were in children and 55 in adults, 85 male and 15 female. In 30 cases occuring in childhood the fracture involved the middle third of the bone, in 10 cases the upper third, in 5 cases the lower third. Nineteen of these patients were totally disabled for two months, 15 for two and a half months, 10 for three months, 1 for five months. There was a further partial disability averaging two months. In 14 cases there was no shortening; in 2 the shortening was ½ cm.; in 18 the shortening was 1 cm.; in 8 the shortening was 1.5 cm.; in 3 the shortening was 10 cm. There was no disability in 30, but 11 of these suffered from slight limp, stiffness, and pain in wet weather. There was slight permanent crippling in 7. There were 2 cases of delayed union.

In the series of 55 cases occurring in adult life, 2 were double fractures. In 32 the fracture involved the middle third; in 17, the upper third; in 8, the lower third. In 2 cases there was no shortening. In the remaining 53 cases, the shortening ranged from 1.5 to 7 cm.

In 12 cases there was no permanent disability; in 43 cases there was permanent crippling, the limp, stiffness, pain, and swelling being so great as seriously to interfere with ordinary activity. The period during which these patients were bedridden was from two to twenty-four months, or longer.

The cases were in the main treated by sand bags and extension, secured by weights attached to the leg and thigh by adhesive strips, the foot of the bed being raised to secure counter-extension.

From a study of the one hundred cases, which Martin says are too few to justify dogmatic assertion, the following conclusions seem tenable:

In children the average period of treatment in bed with crutches, splints, and bandages is five months. In about one-third of the cases there will be no shortening; in about one-half a shortening of 1 cm.; the remainder will show a shortening of between 1 and 2 cm.

In adults the average period of treatment is eight months. In four per cent. there may be no shortening; in five per cent. a shortening of 1 cm.; in nine per cent. a shortening of 1.5 cm.; in twenty-six per cent. a shortening of 2 cm.; in nineteen per cent. a shortening of 2.5 cm.; in seventeen per cent. a shortening of 3 cm.; in twelve per cent. a shortening of from 3 to 4 cm.; and in the remainder an even greater shortening.

An ultimate shortening of less than 2 cm. after fracture of the shaft of the femur in an adult is the exception, and in men past the age of twenty-one years will not occur in more than one case out of ten. An ultimate shortening of from 2.5 to 4 cm. is so commonly observed after skilful treatment of simple fracture of the shaft of the thigh that this circumstance is in itself not even suggestive of carelessness or improper treatment on the part of the surgeon. Martin makes no reference to the fact so emphatically urged and so clearly demonstrated by Thomas G. Morton, that in most cases careful measurement of the human skeleton shows an almost constant deviation from bilateral symmetry. A man with limbs of equal length is, according to Morton, the exception; this he first demonstrated in one of his patients as far back as 1873, when on measuring the two limbs it was found that the fractured limb was slightly longer than its fellow. This led to further investigation, and a series of measurements of different individuals, including those who had suffered injury of the thigh and those who had not, justified the conclusion that asymmetry as to length in the lower extremities of the same person is the rule and perfect symmetry the exception.

"Not more than one man in five who has sustained a simple fracture of the thigh will never again be able-bodied; the other four will suffer from weakness and swelling of the leg and harassing pain, and if laboring-men will be debarred from their usual work."

In speaking of treatment, Martin says that the unsatisfactory results following the weight-extension treatment of fractures of the thigh suggest that this method is either inadequate in itself or is unskilfully applied, or that the ambulant treatment of fractured femur after consolidation of the bone is not sufficiently guarded. If with all the appliances of modern surgery, such as every hospital affords, the results are as described by Martin and confirmed by such authorities as Agnew, Hamilton, Bigelow, and others, those of us in private practice, so far as my limited observation goes, have no special cause for humiliation.

One of the complications, if so it can be termed, sometimes following fracture of the shaft of the femur is what is known as delayed union, differing from non-union in that consolidation eventually takes place. Granted that the fragments are in good apposition and the subsequent treatment combines all that modern surgery approves, it is difficult to explain why in some instances prompt union fails to take place. In such cases I believe the cause can generally be traced to some constitutional vice or fault, which, when recognized and prompt treatment instituted, is followed by good results.

In support of this proposition I ask your attention to the following cases occurring in my practice:

Case I.—On January 20, 1893, S. L——, a young woman seventeen years of age, unmarried, while coasting was violently thrown from a sled against a tree, sustaining a fracture of the right femur at about the junction of its middle and lower third. She was at once carried to her home, placed upon a firm mattress, and sand bags and extension by weight and pulley were employed.

The patient, an exceedingly nervous but intelligent girl, recognized from the start the importance of keeping the fragments in position, and labored in every possible way to avoid disturbance of the limb; so determined was she in this respect that she avoided in so far as possible a regular evacuation of the bowels, although assured of the folly of such a course. Having a most capricious appetite, it was difficult for the first six weeks to get her to take a sufficient quantity of nourishment, although the necessity for this important aid in bone repair was constantly urged upon her. At the end of four weeks the dressings were removed and the limb was carefully inspected. No shortening was detected, but to my chagrin no attempt at union had taken place, notwithstanding the parts were in perfect apposition. The dressings were carefully reapplied. On March 20th, two months after the injury, an examination showed entire absence of bony union. At this juncture I requested Dr. Thomas G. Morton, of Philadelphia, to see the case with me. It was agreed to resort to daily massage of the entire limb, especially in the vicinity of the fracture and to lessen the amount of the extension, the weight at no time exceeding eight pounds. The limb was also incased in a firm dressing made of two Russia-felt splints, carefully moulded to the limb—a posterior one extending from the great trochanter to within six inches of the ankle; an anterior one extending the entire length of the thigh, firmly

held in place by a roller bandage. Four weeks later the patient was allowed to get out of bed daily and walk about on crutches, care being taken that no weight be borne upon the limb. This plan of treatment, together with the daily use of the hypophosphites of lime and soda, was faithfully carried out; the appetite of the patient in the mean time materially improved. In the course of three weeks the circumference of the limb had visibly increased and an evident attempt at bony union was noticed. From this on the limb gradually improved in size and strength, until at the expiration of eight weeks from the commencement of massage, or sixteen weeks from the date of injury, consolidation was complete. The dressings were continued for a few weeks longer, when a roller bandage took the place of splints. Careful measurement of the two limbs failed to show any appreciable shortening. Ultimately no evidence of the injury was apparent to the observer.

Case II.—February 6, 1897. C. L——, male, twenty-six years of age, weight one hundred and sixty pounds, while working in a rubber mill had occasion to move a heavy roll of rubber belting from a platform to a truck below. In some way he slipped to the floor, the roll falling upon his right thigh, causing fracture of the bone both at its upper and middle thirds. He was conveyed to his home, a distance of eight miles. With the assistance of Dr. Macfarland, of Bordentown, the patient was etherized and reduction of the fracture was made. The treatment in this instance was essentially like that employed in Case I., except that the limb was encased in the felt splint at the initial dressing, and for the outer sand bag was substituted a well-padded wooden splint, long enough to extend from four or five inches below the axilla to about five inches below the heel, four and one-half inches wide by one-half inch in thickness. At the lower extremity of the splint was attached a cross-piece, two feet long by three or four inches wide and half an inch thick; the object being to prevent tilting of the splint and consequent reversion of the limb. This splint is recommended by Hamilton, of New York, for all fractures of the thigh, and is, I think, superior to the sand bag as an outside splint. The case apparently progressed satisfactorily. In this instance, as in the first case, the patient was of a very nervous temperament, but possessed of a fairly good appetite and digestion.

On removing the dressings at the end of four weeks no union whatever had taken place. The bandages were reapplied, and two weeks later the limb was again examined; still no union. Two weeks later there seemed to be a slight attempt at consolidation in the upper fracture, but none in the lower. I now began the use of hypophosphites of lime and soda, together with daily massage. In the course of three or four weeks longer I was gratified to note bony union throughout. The patient was now allowed to get about on crutches, the massage and hypophosphites being meanwhile continued. What gave me more or less concern was a feature that played no part in Case I., namely, almost complete ankylosis of the knee joint. Not to prolong the history of the case, the patient in about four months from the time of accident was able to bear some weight upon the injured limb; but it was fully nine months before he ventured without the support of a cane. Ultimately he, too, made a good recovery, save for about three-quarters of an inch shortening and some remaining stiffness, both of which cause a perceptible limp, but in no sense interfering with his ability to do a hard day's work.

These cases teach several lessons: (1) Delayed union is possible notwithstanding the conditions for repair are apparently every way favorable; (2) consolidation is readily effected by systematic employment of massage and the use of the hypophosphites; (3) the advisability of the early employment of massage in thigh fractures, say as early as the fourth week, both for the purpose of facilitating consolidation by improving the nutrition of the parts and to prevent knee stiffness or ankylosis, a not infrequent accompaniment of such injuries; (4) the early use of the hypophosphites of lime and soda in all cases of fracture when there exists doubt of prompt bony union.

The Use of Inflammation-Producing Agents in the Treatment of Wounds.—G. Meyer takes the stand that absolute asepsis is impossible, and that, no matter how nearly perfect the operative technique, there will still inevitably be some infection of the wound. Inflammation is now universally regarded as a conservative process, and its production in a mild degree means an increased power of resistance of the organism through the more active formation of bactericidal toxins. Arguing along these lines he advocates the use of some mildly irritant application to the neighborhood of the wound; tincture of iodine answers every purpose, and gives the requires stimulus without in any way jeopardizing asepsis.—*Centralblatt für Chirurgie*, August 11, 1900.

Subphrenic Abscess following Appendicitis.—J. F. Baldwin reports two cases, which make the forty-fourth and forty-fifth on record. In the first case, that of a woman aged forty-nine years, the appendix was removed by inversion in June, 1899. Convalescence was satisfactory, but in two weeks' time pain and soreness reappeared above the location of the appendix. On July 20th a large abscess pointing on the right side at about the tip of the twelfth rib was opened, and gave exit to an enormous amount of pus. In the second case, that of a young girl aged sixteen years, a gangrenous and perforated appendix was removed on July 26th, and convalescence was uninterrupted. From August 16th to 28th, however, the patient had irregular fever, with rapid pulse and profuse perspiration. There was no bulging, but the septic condition called for interference. An exploratory incision showed a pus cavity back of the suspensory ligament of the liver, which was evacuated and drained. Recovery was prompt, abscess and wound healing in about two weeks.—*Cleveland Journal of Medicine*, August, 1900.

A Case of Anthrax Successfully Treated by Local Injections of Pure Carbolic Acid.—W. E. Fisher relates an instance of anthrax, which he considers a comparatively rare disease in this country. The lesion developed on the forearm seven days after a punctured wound. On the eighth day swelling was followed by a bluish-colored bleb one-eighth inch in diameter. Cultures showed the anthrax bacillus. The temperature was 104° F. The lymphatics of the axilla were not painful or enlarged. Nausea, malaise, and the same high temperature persisted under wet bichloride dressing till the next day, and new blebs of bluish color formed about the site of puncture. One drachm of ten-per-cent. carbolic solution was now injected into and around the eschar. Pure carbolic acid in drachm doses was continued for six days, and the conditions improved, while no carbolic acid was detected in the urine. After the third injection the temperature fell to normal, and after the fifth the eschar ceased spreading. Jarnovsky reports seventy-two cases treated in this manner in which cure resulted. Other forms of treatment recommended are bichloride injections, the internal use of large doses of ipecac, and excision.—*Therapeutic Gazette*, August, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 22, 1900.

EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

THERE is hardly need to emphasize the importance of early recognition of pulmonary tuberculosis in order that appropriate treatment may be promptly instituted. Tuberculosis is no longer properly synonymous with consumption or phthisis, for we have learned that restoration to health takes place in a large number of cases, sometimes with, sometimes without the intervention of therapeutic art. It is true that for practical purposes one must make a distinction in this connection between anatomical and clinical recovery. The latter implies subsidence of activity on the part of the morbid process and cessation of clinical symptoms. It may be associated with fibroid changes in and encapsulation of the tuberculous lesions, in which, however, tubercle bacilli, while perhaps not actually destroyed, are rendered innocuous, for the time being at least.

The good that can be accomplished by treatment must be effected early for the attainment of the most satisfactory results, and existing records should stimulate the physician to his best endeavors to bring about such a desired end. The diagnostic difficulties are by no means inconsiderable, inasmuch as the disease may, and often does, have a most insidious beginning, and it may have progressed considerably before ordinary physical signs and symptoms become obvious. Some of the more important and valuable of these are dwelt upon by Strauss (*Berliner klinische Wochenschrift*, 1900, Nos. 25 and 26) in an address delivered a short time ago before the Association of German Railway Surgeons. It was pointed out that inspection should be general as well as local. The preservation of the general nutrition is of less importance than its impairment, and the absence of the tuberculous habitus than its presence. Comparative inspection of the upper part of the chest on both sides, particularly with reference to its length and breadth and the respiratory expansion at the apices and in the infraclavicular region, is more important than a consideration of the general conformation of the chest. In some persons predisposed to pulmonary tuberculosis the acromial extremity of one clavicle, generally the right, occupies a lower level than that of its fellow.

Percussion frequently does not yield so much information as auscultation. The topographic are more important here than the qualitative results, and are obtained by exact determination of the expansion of the apices upward (by percussion from above downward) and outward (by percussion anteriorly from the acromion toward the middle line). High-pitched tympany is of considerable diagnostic significance. All of the signs yielded by percussion, as well as by auscultation, are, however, of value only when considered in association with other signs. The significance of the auscultatory phenomena is all the greater the more they are confined to one apex, especially the posterior portion of the right apex. In some cases, however, symptoms of diffuse bronchitis predominate, especially in persons who have been exposed to the inhalation of dust. Nor does the presence of emphysema or of disease of the heart necessarily exclude the existence of tuberculosis. Occasionally auscultatory phenomena indicative of tuberculosis are found in other portions of the lung than the apex, as, for instance, just below the clavicle or at the base between the mammillary and the anterior axillary line, while percussion of the anterior aspect of the chest often yields better results. The reverse is true of auscultation. Muscle-murmurs or physiological crepitation on deep inspiration should not be mistaken for râles. It is of great importance to find that the abnormal physical signs are always present in the same situation on repeated examination. Auscultatory phenomena may be rendered more obvious by cough or by the administration of small doses of potassium iodide for the purpose of increasing the secretion of an already irritated bronchial mucous membrane.

Evidence of active disease will be afforded by the presence of certain constant symptoms, especially progressive loss of weight and fluctuations in temperature, and also anæmia or chlorosis and their sequelæ, symptoms of irritability or of exhaustion of the nervous system, especially of the cardiac nervous apparatus, and signs of digestive derangement. Of especial significance are certain symptoms that, while not arising directly from the lungs, point to disease in the air-passages, such as persistent hoarseness, which should lead to laryngoscopic examination. Night-sweats, transitory flushing of one cheek, chest-pains, radiating pains in the muscles of the shoulder, should likewise suggest examination of the lungs. Especial consideration should be given to hæmoptysis or to pleurisy, present or past. The former should be considered a symptom of pulmonary tuberculosis until proved otherwise, and the latter is always highly suspicious, as about one-half of the cases of pleural effusion of obscure origin are tuberculous. In order to establish the diagnosis some of the fluid obtained on exploratory puncture should be injected into the peritoneal cavity of a guinea-pig, and the results that take place in six weeks awaited.

In the history some importance is to be attached to hereditary influences, to general and local lowering of the powers of resistance, and to association with tuberculous patients. No one or all of the symptoms mentioned are definitely conclusive as to the existence of pulmonary tuberculosis. For this the demonstration of tubercle bacilli in the sputum is necessary. Fail-

ure to detect the bacilli does not, of course, exclude the existence of tuberculosis, as the micro-organisms can appear in the sputum only when communication exists between a softened tuberculous focus and the bronchial apparatus. Should tubercle bacilli not be demonstrable in the presence of other symptoms of tuberculosis, the tuberculin test should be employed; but it should be borne in mind that a reaction will be obtained whatever the situation of the tuberculous lesion.

THE PRESENT STATUS OF BACTERIOLOGY.

Though one of the youngest of the medical sciences, bacteriology has had a most rapid, yet withal lusty growth in recent years. It is true that great and many changes in hypothesis and theory have been necessary with advances in knowledge, but this is a natural evolutionary process. Great progress in etiology and prophylaxis has been made, and the promise of therapeutic success has been in part fulfilled; but many problems yet remain to be solved, many obscure points to be cleared up. Of the present status of bacteriology a most interesting summary is given in a didactic article by Baumgarten (*Berliner klinische Wochenschrift*, 1900, Nos. 27 and 28). He points out that bacteria are still classified, not in conformity with the principles of natural history, but in accordance with their morphological appearances. Such classification is, however, based upon more than the external characteristics, in so far as the several forms, apart from minor variations, never pass one into another. Nor does the knowledge that bacteria that under natural conditions exert definite effects, and should, therefore, be designated specific, under artificial conditions exert effects approximately those of other species justify the assumption that the individuals of one species pass over into those of another. It is true that atypical cultures can be maintained under certain conditions, but a return to the normal takes place when these conditions are removed.

The bacterial cell is a more or less solid structure, consisting of a protoplasmic body (by some thought to be a nucleus) contained within a membrane, and surrounded by a more or less distensible sheath (by some considered to be the cell body). It is generally free from chlorophyl, only a few containing an allied pigment (bacterio-purpurin). In addition to molecular movement, bacteria may be propelled by flagella. Multiplication takes place by fission; perpetuation through spores occurs only as the result of a provision of nature in case of necessity, in order to defer proliferation to a more propitious time, when the mature cells are surrounded by conditions not favorable to multiplication.

A study of the vital conditions of bacteria has shown that it is their function to convert the refuse of the organic world so that, eliminated from the living, it shall be adapted to enter the sphere of life again, and that which never possessed life is introduced into organic life. The bacteria induce in the products of organic life, in organic but not organized substances, not dead but not living, in which the molecules have reached a state of relative rest, movements or activities that constitute the distinctive feature of ferments or zymotic bodies. Others invade active life, being naturally true parasites, and thus pathogenic, entering the animal body and vegetating therein. In order that the latter result shall take place, the bacteria must find the necessary conditions for their existence. The absence of these constitutes natural immunity.

If the bacteria find lodgment and undergo multiplication, they induce disease, which is an expression of the reaction of the body to irritating influences. Some of the resulting symptoms, such as fever and inflammation, are due alike to various bacteria, but in general each micro-organism gives rise to a peculiarly characteristic and distinctive symptom complex and course. Bacteria constitute the specific cause for a number of specific diseases: the diseases are specific because the bacteria are specific. The infecting micro-organisms and their injurious effects may remain confined to the site of invasion, or the products of their activity may be taken up and distributed by the circulating fluid. A number of bacteria, however, proliferate only in the blood or in remote parts, or simultaneously at the site of inoculation and in both of these. The bacteria whose effects are due principally to the poison to which they directly or indirectly give rise have long been designated toxic, in contradistinction from those that give rise to symptoms by reason of their enormous multiplication within the body, and which are designated infective.

The bacteria live and multiply at the expense of the cells and the tissues, and, without diminution in the volume of the plasma, they so alter the chemical constitution of the molecules by selective action that the cell or its derivatives are starved and die in consequence of disintegration of the plasma, or are stimulated to the formation of cells that are incapable of performing the specific function of the mother cell. The elimination of a large number of important cells from the economic apparatus of the living body in this manner or their perverted functions may, in accordance with the parts affected, be manifested in various forms of disease. As in the cells, bacteria, when they multiply in the blood, would be capable of harm not only through impoverishment of the blood, by the taking up of nutritive matters, but also by interfering with the organic associations of these substances at innumerable points. A mechanical factor may also be present, the bacteria surrounding the blood corpuscles, occluding the capillaries, giving rise to thrombi, preventing interchange between the blood and the cells.

The bacteria are capable through their secretions of converting nutrient material into poisons, which are sent to all parts of the body, where they enter into relations with parts for which they have chemical affinity, giving rise to nutritional changes and functional disturbances and thus to the characteristic outlines of the clinical picture.

In addition to these specific poisons there occur also substances derived from them and not possessing similar activity—so-called toxins; and others that are common to various bacteria and cause similar effects, such as fever and inflammation. Then also certain

effects are attributable to absorption of substances generated in considerable amount from decomposition of the nutrient substratum. The symptoms of intoxication are thus due to several factors and are accordingly variable. The assumption of a multiplicity of poisons generated by specific bacteria affords an explanation not alone of the variability in virulence of epidemic bacterial diseases, in accordance with the amount of the specific poison, but also of the character peculiar to almost every epidemic.

As the bacteria find the conditions for their proliferation only where they can enter into interchange with the nutrient medium, so the possibility of activity on the part of the poisons produced by them presumes a reciprocal relation between the poison and the part attacked; that is, the bacterial poisons are not injurious everywhere or to all of the tissues of the body; they are not omnipotent. Upon this exclusiveness of action upon certain cell-territories is in part dependent the claim of specificity for the bacteria. It is believed that the poisons enter into chemical combination with the structure of the cell, rather than that they merely cause injury to the cell without entering into its structure, by inhibition of its functional activity through simple contact. The poison is neutralized, probably in some instances at least, not by substances generated by the bacterium itself or from its own transformation but through the activity of the invaded body, which is stimulated to the production of a counter-poison.

Active immunization, *i.e.*, the conferring of protection against fatal amounts of bacteria or their toxins, not only has been of great service in practical therapeutics, but it has also shed much light upon the causation of the immunity induced naturally or artificially by recovery from disease. Artificial active immunization may be looked upon as the analogue or successful experimental imitation of natural immunity, the antitoxin being prepared by the cells of the body as a result of influences exerted by the toxin. Recovery from disease with the final elimination of the bacteria is thought to take place through a process of bacteriolysis by the action of a ferment set free in the blood through cellular activity.

News of the Week.

Dr. Ellwood R. Kirby has been appointed by the mayor of Philadelphia a member of the bureau of charities and correction.

The Dangerous Celluloid Comb.—A young woman in a town near Philadelphia was recently burned about the head from the combustion of celluloid combs worn in the hair. The accident resulted from the practice, in itself not free from danger and scarcely to be commended, of putting burning joss-sticks in the hair for the purpose of keeping away mosquitos.

A Parsee Woman Physician.—The first Eastern lady admitted to the licenses of the Royal College of Physicians and Surgeons in Ireland, and the first, according to the belief of the *Medical Press*, to be admitted to any qualification in Great Britain, received her diplomas recently. The lady is a Parsee named Miss Aunnie M. Treausurywala, and she appeared at the capping ceremonial in the full costume of her caste. She made a most brilliant examination for her final, having been the only candidate who passed with honors.

An Edict Against Long Skirts.—The local board of health in one of the districts of Vienna has placed placards in all the public gardens and parks, directing the women who visit these places to hold up their skirts if they trail upon the ground. The notice states that as these enclosures are devoted to the recreation of persons desirous of escaping from the dusty town, the authorities forbid dust to be swept there into heaps by trailing skirts.

The Royal Disease.—Dr. Bachmann, of Shanghai, has recently stated, in a letter to the *Gegenwart*, that Emperor Kwang-Su suffers from cancer of the throat, and is unable to reign. The same view is taken by Dr. Dethère, a French physician, and by Dr. Sheng Lian Feng, both of whom have examined the emperor. This seems to be the disease to which rulers are specially prone.

Threatened Famine in Ireland.—Fears of a potato blight and failure in the grain harvest in Ireland are beginning to be expressed, and priests recently returned from that country say that the outlook for the natives of the Green Isle this winter is fast becoming as serious as that of the famine years of 1846 and 1847, when nearly two million people died as the result of the blight of the potato crop.

Anti-Rabic Inoculations in Paris.—During the years 1886-99, or since the Pasteur Institute in Paris was founded, 23,245 persons, suffering or supposed to be suffering from the bites of rabid animals, have been treated there by means of preventive inoculations. Of this number only 103 died. The figures for each year are as follows:

Year.	Number of Persons Treated.	Number of Deaths.	Rate of Mortality. Per Cent.
1886	2,671	25	.94
1887	1,770	14	.79
1888	1,622	9	.55
1889	1,830	7	.38
1890	1,540	5	.32
1891	1,559	4	.25
1892	1,790	4	.22
1893	1,648	6	.36
1894	1,387	7	.50
1895	1,520	5	.33
1896	1,308	4	.30
1897	1,521	6	.39
1898	1,465	3	.20
1899	1,614	4	.25

Protest against Vaccination.—A report from Berlin states that owing to the unusually heavy passenger traffic, as well as to the reduction in number of passenger steamers, many American citizens have recently been compelled to take steerage passage in returning to the United States. The physicians of the North German Lloyds Steamship Company have very properly insisted upon vaccinating all these to meet the re-

quirements of the United States laws. Recently an American filed objections with the United States consul at Bremen, who wrote to Washington for instructions, meanwhile forbidding the physicians in question to vaccinate Americans in the steerage on the ground that the law was intended to apply to immigrants only. We do not know whether or not an American consul has the right to set up his authority against the law of his country, but in any case it is cruel to deprive any man of the security afforded by vaccination just because he happens to be an American citizen.

Dr. Archibald Church has been recently appointed professor of nervous and mental diseases and head of the neurological department in the Northwestern University Medical School (Chicago Medical College).

The Southern Surgical and Gynæcological Association.—The next annual meeting of this association will be held in Atlanta, on November 13th, 14th, and 15th, under the presidency of Dr. A. M. Cartledge, of Louisville. Members of the medical profession are invited to attend.

The Woman's Medical College of Philadelphia.—Dr. W. L. Rodman has been appointed professor of the principles and practice of surgery at the Woman's Medical College in Philadelphia, and Dr. W. V. Laws has been appointed professor of operative and clinical surgery at the same institution.

Dr. William C. Woodward has been reappointed health officer of the District of Columbia, and the order of 1894, limiting the term of office to three years, has been suspended. This secures to Washington the services of a particularly efficient commissioner of health.—*Maryland Medical Journal.*

Tuberculosis has now been declared officially to be a disease subjecting the sufferer to quarantine. In the case of a Japanese with tuberculosis recently arrived at San Francisco, the Commission of Immigration has decided that the disease is contagious and that the sufferer cannot land and must return to the port whence he sailed.

Dr. Julian Calleja y Sanchez, professor of descriptive anatomy and embryology at the University of Madrid, has been chosen president of the Fourteenth International Medical Congress, which will meet in Madrid in 1903, and Dr. Fernandez y Caro, inspector-general of the Spanish navy, has been appointed secretary general of the congress.

A Vegetarian Colony.—The president of the Vegetarian Society of America is in the South looking for a suitable place where members of the society can establish a colony. Association with meat-eaters is said to become disagreeable to real (no-egg, no-milk) vegetarians, and so they wish to flock by themselves. They want to go to a place where all sorts of fruits and vegetables can be grown, and if a suitable one is found many of the members of the society will go there and engage in fruit and vegetable farming and in the manufacture of preserved fruits and peanut butter.

Phosphorus in Oysters.—Some French chemists have recently made very extensive analyses of several varieties of oysters in order to ascertain the quantity and form of phosphorus which exists in these toothsome bivalves. They found that a dozen Portuguese oysters contain about six grains of phosphoric acid, which represents about fifteen grains of the tribasic phosphate of lime. About four grains per dozen was obtained from French oysters.

Typhoid Fever at the Children's Asylum in Syracuse.—The annual epidemic of typhoid fever has broken out in the State Custodial Asylum for Feeble-Minded Children at Syracuse, and twelve persons are down with the fever, including the resident physician. Every year it has been thought that the cause of the disease had been eradicated, but its recurrence again has led the State board of health to undertake a thorough investigation of the origin of the infection.

An Alleged Death from X-Ray Burns.—A death certificate recently presented to the St. Paul board of health stated that the deceased came to his death in consequence of burns received during an examination by means of the Roentgen rays. The man met with a street-car accident last winter, and, it is said, desired to have *x*-ray photographs taken of his injuries for use as evidence in a suit for damages. The doctor who took the radiographs denies that the patient was burned so seriously as to cause fatal injuries.

A Medicine Man's Failure.—The penalties for insuccess in therapeutics are somewhat severe at times among the aborigines as well as in civilized communities. Not long ago Illowaho, an aged medicine man and chief of the Yakima tribe, in the State of Washington, was stoned to death in his tent by an Indian named John. He had been called to save John's child, who was sick, and went through the usual formalities, with no more success than a "Christian scientist." The child died, and the enraged father went to the medicine man's tent and stoned him to death.

The Standardization of Antitoxins. — A firm of manufacturing chemists in England having applied for a license to perform experiments upon living animals for the purpose of standardizing antitoxins, the Royal College of Physicians was requested to give an opinion as to the advisability of granting the license. The reply of the college was that, while these experiments were absolutely necessary to the advance of pharmacology, the granting of such licenses to commercial firms was very undesirable. The standardization of antitoxins should be done in a government laboratory, into which the question of money-making did not enter.

An Unfortunate Decision.—A judge in Towanda, a Pennsylvania town, has just reversed a judgment by which $2, the penalty for non-attendance at school, was recovered by the school board from a Christian Scientist who declined to have his son vaccinated, in consequence of which the latter was refused admission to the school. The judge expressed the opinion that the vaccination law is not mandatory, but optional,

and that the parent did all the law required in sending his son to school, although the latter was refused admission. This opinion is opposed to that expressed recently by a learned Philadelphia judge, who declared in favor of the validity of the compulsory vaccination law.

Fatal Hemorrhage from Ritual Circumcision.—The death is reported at Philadelphia of a Jewish child, fifteen days old, as a result of hemorrhage following the performance of circumcision as a religiousrite.

The American Academy of Railway Surgeons met in seventh annual session in St. Paul on September 5th and 6th, under the presidency of Dr. Charles A. Wheaton, of that city. The election of officers for the ensuing year resulted in the following choice: *President*, Dr. D. S. Fairchild, of Clinton, Ia.; *First Vice-President*, Dr. W. L. Estes, of South Bethlehem, Pa.; *Second Vice-President*, Dr. W. J. Mayo, of Rochester, Minn.; *Secretary* and *Treasurer*, Dr. T. B. Lacey, of Council Bluffs, Ia. The next meeting will be held in Chicago.

The British Hospitals in South Africa.—The testimony which is gradually coming in regarding the conditions of the medical relief service in the Boer war tends to offset the exaggerated statements of Burdett-Coutts, Kipling, and others. Medical men and laymen who were on the spot, and saw with their own eyes what they describe, admit that at Bloemfontein and Kroonstad there was some extra suffering when the pressure became great, owing to the lack of skilled orderlies, but there was nothing to warrant Mr. Burdett-Coutts' statements. During Roberts' march there was some difficulty in coping with the sick and wounded. For the first sixteen days the Bloemfontein supply trains that arrived were insufficient for the daily requirements. Then they began slowly to accumulate a reserve until they had forty-five days' stock when they moved forward. The wounded were sent back with the least possible delay. General Roberts frequently visited the hospitals and was satisfied that the surgeons did their duty. The commissioner of the Red Cross Society at Cape Town reported only recently that he had visited the hospitals at Pretoria, Johannesburg, and other centres of operations, and had found the arrangements for the care of patients excellent and the hospital supplies abundant. Dr. Ryerson, who was the Canadian Red Cross commissioner in South Africa, stated a few weeks ago that the hospital arrangements could not have been more admirable. In war, one could not expect the same comforts, hospital and otherwise, as in peace, but nothing that was deemed necessary was wanting. What astonished him especially, Dr. Ryerson said, was the testimony of Kipling that medicine had been taken into the hospitals by the back door. There was no necessity for taking it in surreptitiously, he asserted, and no reason why the surgeons should have so received it.

Conjunctivitis is very prevalent in New York, and the eye clinics are reported to be thronged with sufferers from this unpleasant malady. It is attributed by some to contagion acquired in the public baths.

A Congress of Polish Medical Men was recently held at Cracow. The opening address was delivered by Professor Kostanecki, who took as his theme the universality of medical science. The two principal subjects discussed during the general sessions were the means of combating tuberculosis and alcoholism. The work of the congress was divided among twenty-four sections, and there was a large attendance of physicians from the three divisions of Poland.

Vacancies in the Naval Medical Service.—A board for the examination of candidates for admission to the medical corps of the navy is in session at the Naval Laboratory, Brooklyn, N. Y., and will remain in session for several months. There are now seventeen vacancies in the list of assistant surgeons. Congress at its last session passed a law taking assistant surgeons out of the steerage and making them ward-room officers as soon as they entered the service, giving them the rank of junior lieutenants and the pay of assistant surgeons in the army. Candidates must be between the ages of twenty-one and thirty years. A circular of information can be obtained on application to the surgeon-general of the navy, Navy Department, Washington.

The "Maine" at Wei-hai-Wei.—The medical officer on the hospital ship *Maine*, which was equipped for service in South Africa through the contributions of Americans and afterward went to China, cables to the London committee under date of Wei-hai-Wei, September 13th, that the vessel has been ordered to remain at that port and await the arrival there of sick and wounded.—*The Sun.*

The State Hospital for Tuberculosis.—The New York board of pensions recently passed a resolution recommending that the State Hospital for Consumptives be erected at Dannemora. This place, where there is already a penitentiary, is in the Adirondack region. The hospital commission has a number of sites under consideration.

The Marine-Hospital Station at Biloxi, on the Gulf of Mexico, concerning the safety of which grave fears were entertained at the time of the Galveston disaster, escaped all damage from the hurricane.

A New Epileptic Colony in England.—The David Lewis Trustees, who have the disposal of a large sum of money left for public charities, are engaged, the *British Medical Journal* states, in completing arrangements for a munificent gift to the public, representing a sum which may possibly approach £100,000. There were negotiations a year or two ago between the trustees and authorities of the Southern and St. Mary's hospitals, Manchester, with a view to the presentation to the city of a hospital for women, which was to cost about £60,000. These negotiations fell through, but the trustees have now decided to purchase a considerable estate at Warford, near Manchester, where preparations are being made for the erection of extensive buildings for the accommodation and treatment of epileptics. Every effort will be made to produce a thoroughly efficient modern institution in which the most advanced scientific treatment may be given. The new

colony will not be designed for the reception of pauper patients, and will be distinct from the undertaking of a joint committee of the Manchester and Chorlton unions, which is said to contemplate the erection of a hospital to accommodate about one thousand epileptics and imbeciles.

Health Conditions in Havana.—The mortality report of Havana for August, including deaths from all causes, shows a lower total than for any previous August in ten years, the figures being 559 as against 620 in 1899 and 1,978 in 1898. The death rate for August was 2.76, yellow fever furnishing 49 victims and tuberculosis 65. On September 13th there were 78 cases of yellow fever in the city. *La Habana Médica* says that the gravity of the present epidemic of yellow fever in the city is truly alarming. In 1895 the number of cases was greater, but the general character of the disease was fairly mild. This year, however, the gravity of the fever is marked, the mortality exceeding thirty per cent. Thus yellow fever continues to dominate among the local diseases, while other diseases are decreasing with the improvement in hygiene. Our contemporary despairs of controlling the disease by hygienic measures only, and says that it can be conquered by some effective specific remedy, which as yet is wanting.

Report of Cholera in Madrid.—An alarming despatch from Madrid was sent out last week stating that Asiatic cholera had appeared in that city. Investigation, however, showed that the disease was simply cholera nostras, of which numerous cases occur every summer.

The Congress of Spanish Surgeons was to have held its second meeting in Barcelona in September, but in view of the meeting of the Thirteenth International Medical Congress at Paris this summer the organizing committee decided to postpone the meeting until the autumn of 1901.

Fire in City Hospital.—A defective flue on the fourth floor of Charity Hospital on Blackwell's Island caused a small fire there one afternoon last week. The call brought a lot of fire apparatus to the foot of East Twenty-sixth Street, and a steamboat was all ready to hurry it over to the island, when a telephone message was received saying that the fire was out. There was no damage and little alarm was caused among the patients.

British Mortality in the Boer War.—A careful analysis of the statistics shows that of the British officers in South Africa 72.1 per thousand have been killed or have died from wounds, and 30.6 per thousand have died from disease. Of the men, 19 per thousand have been killed or died from wounds, and 31.8 per thousand have died from disease. These statistics show that, while the officers and men suffered nearly equally from disease, the risks of the officers in action were greatly disproportionate.

The Plague in Glasgow continues with an occasional new case, the number of suspects being one hundred and sixteen, and of declared cases twenty-two. On September 17th five new cases were discovered. They were in the persons of the wife and two children of a hospital worker and his mother and sister. It seems that they had been in constant contact with suspected plague cases since August 22d, and had been ill without the knowledge of the authorities. The family comes from the neighborhood where the plague appeared at first. This new outbreak has caused some uneasiness in the public mind, as it suggests that the health authorities are not completely in control of the situation. In Hong Kong the epidemic has abated by the efforts of the health authorities or has exhausted the soil upon which it formerly thrived. For the first week in September four cases and four deaths were reported.

The Search for the Missing Link.—It is stated in *Science* that Mr. George Vanderbilt is defraying the expenses of an expedition to Java by Mr. David J. Walters of New Haven, who purposes to search for remains of Pithecanthropus erectus.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 15, 1900. September 7th.—Assistant Surgeon C. A. Crawford detached from the *Eagle* and ordered to the *Dixie*. September 8th.—Surgeon M. F. Gates detached from the naval hospital, Norfolk, Va., September 12th, and ordered to the *Atlanta*, September 15th. Passed Assistant Surgeon A. M. D. McCormick ordered to the naval hospital, Norfolk, Va., for duty, when detached from the *Montgomery*. September 12th.—Passed Assistant Surgeon L. Morris detached from the *Baltimore* when put out of commission, and ordered home and to wait orders. Pharmacist J. Pearson detached from the *Wheeling* and ordered home and to wait orders. September 13th.—Assistant Surgeon W. E. G. High detached from the naval hospital, Yokohama, and ordered to the *Oregon*.

Obituary.

HUNTER McGUIRE, M.D.,

RICHMOND, VA.

Dr. Hunter McGuire, of Richmond, Va., died September 19th, at his country residence near Richmond, Va., as the result of exhaustion from hemiplegia, with which he was attacked six months ago.

For a long period he maintained the proud position of the leading surgeon of the South, and his loss to the profession and his numerous friends and admirers is irreparable. Identified with all matters tending to the advancement of the interests of his calling, a writer of authority, and a leading and distinguished educator, he exerted an influence for good along many and varied lines, which can scarcely be overestimated. He was born at Winchester, Va., October 11, 1835, his father being Dr. Hugh H. McGuire of that place. His early education was in his native town, where he also commenced his medical studies, completing them in the Winchester Medical College in 1855, and the following year in Philadelphia. He first located in Winchester, assisting his father in practice, and occupying

the chair of anatomy at Winchester Medical College. In 1858 he resided temporarily in Philadelphia, and after distinguished service in the Confederate army as chief medical officer on Gen. Stonewall Jackson's staff, he settled in 1865 in Richmond. Here his success in practice and his influence as a leader of medical thought became assured from the first, and in 1869 he was made president of the Richmond Academy of Medicine. He was also president of the Association of Confederate Officers, and was one of the vice-presidents of the International Medical Congress of 1876.

His voluminous and varied writings on surgical subjects proved him a thorough scholar, a skilled anatomist, and a judicious and conservative counsellor. As an occasional contributor to general periodical literature he took a high rank, which was well deserved after his admirable and touching history of the death wounds of Stonewall Jackson.

He was a hard and constant worker, but his main ambition centred in the foundation and prosperity of the University Medical College of Richmond, with which he was so long and honorably identified.

Obituary Notes.—Dr. John McMahon Brown died of cardiac trouble at his home in this city on September 12th. He was born in Ireland fifty-five years ago, and was graduated in medicine from the University of Dublin in 1868. He practised for many years in Dublin and later in London, and came to this country in 1888. He was a visiting physician to the Metropolitan Dispensary.

Dr. Frank C. Merriam of this city died at Waterford, Conn., on September 16th, at the age of forty-six years. He was a graduate of the University Medical College in 1880. He had been in poor health for over a year.

Progress of Medical Science.

Boston Medical and Surgical Journal, Sept. 13, 1900.

Actinomycosis.—Charles Allen Porter reports eight cases with the object of attracting attention to the possibility that a proportion of the cases ranking as alveolar abscesses may be due to the specific organism of this disease. Though it cannot be a rare affection, he says, few cases enter the hospital with advanced actinomycosis of the jaw, and it seems therefore certain that many recover after simple incision of the abscess, and even through a natural rupture of it. Simple opening, curetting, and drainage have proved sufficient in many cases; though recurrences may be frequent, healing eventually takes place. When possible, excision of the inner half of the abscess wall or sinus is the best treatment. The danger from swallowing the granules, when the discharge empties into the month, is hard to estimate. Certain cases of generalized disease in the lungs, intestinal tract, liver, etc., occur in which the organism gained entrance through the food, or was swallowed, and therefore the surgeon should aim at making external drainage.

Tendon Suture.—Edward S. Hatch describes the case of a patient who plunged his right hand through a window and cut the anterior part of his wrist on the ulnar side. The tendons of the palmaris longus, flexor carpi ulnaris, and flexor sublimis digitorum were found to be divided. The ulnar artery and the median nerve were also found to be cut. The ulnar nerve was cut about half-way through its structure. The tendons and nerves were united with fine silk sutures. The ulnar artery was tied, both the proximal and distal ends. No attempt was made to unite the tendon sheaths. The skin wound was united with interrupted silkworm-gut sutures. The results of the operation were excellent. At the present time, seven months later, the patient has normal flexion and extension, with normal sensation over the distribution of the median nerve. He can separate the fingers and draw them together again with perfect ease.

The Radical Cure of Hernia.—J. Collins Warren, urging the radical operation rather than the wearing of a truss, gives statistics of a series of ninety-eight cases operated upon between 1888 and 1900, showing in a striking way the marked change which the improvement in aseptic technique has brought about in the prognosis of the healing of the wound. Prior to 1895 there were thirty-three cases operated upon, of which sixteen, or forty-eight per cent., were septic; whereas, after 1895, of sixty-five cases operated upon, nine, or sixteen per cent. only, were septic. The term "septic" includes all cases that did not heal by first intention throughout the wound. The slightest infection of a stitch would place it under the above heading. When silk was used for sutures only seventeen per cent. of the wounds were septic, but in the case of catgut septic conditions were found in forty per cent. The author describes several points in the technique of the operation.

Four Cases of Actinomycosis.—John C. Munro reports four cases, in one of which the tumor was situated below the angle of the scapula. The three face cases showed invasion of the soft tissues only, the bone being free. In none of them could any definite trace of the original affection be found. All the patients were given iodide of potassium, and the wounds were treated with peroxide, tincture of iodine in full strength or solution, and packed in iodoform gauze until all evidence of presence of the fungus had disappeared.

A Method of Teaching Practical Medicine.—By Thomas F. Harrington.

The Medical News, September 15, 1900.

Post-Apoplectic Temperature and Disturbances of the Alimentary Tract: their Management.—Henry Lyle Winter believes that a continued high temperature, at times irregular in its fluctuations, and various disturbances of the digestive organs, usually of the fermentative type, which occur frequently after cerebral apoplexy, may be dependent entirely upon the absorption of the infective material in the alimentary canal. Hitherto these symptoms have been met with small doses of calomel, but the writer thinks hydrogen dioxide much more effective. After its administration he has found that it not only improved the condition of the alimentary tract, but that the temperature subsided. It has been his practice to give the drug combined with an eqnal quantity of chemically pure glycerin.

In What Relation does Occupation Stand to Tuberculosis?—In studying the statistics of tuberculosis as related to occupation, W. Freundenthal notes one striking fact, viz., the extraordinary large number of tailors and those with similar occupations who suffer from this disease. The writer finds the causes for this condition of things in lack of exercise, bad ventilation, overwork, undernutrition, and lack of all hygienic precautions, resulting in that condition christened by Bouchardat "physiological misery." His general conclusions are in accordance with Flint's, "that occupation has an agency in the etiology of pulmonary tuberculosis, in so far as it is sedentary and involves confinement within doors."

A Simple and Efficient Treatment of Talipes Calcaneus Paralyticus in Young Children.—Dr. V. P. Gibney reports several cases evidencing the efficacy of prolonged and uninterrupted extension of the foot. The writer prefers a plaster-of-Paris dressing, but says that almost any appliance which is worn night and day, the management of which is taken completely out of the patient's hands, should bring about like results. He has not resorted to the method in older patients, for the reason that it is difficult to keep plaster of Paris on a limb sufficiently long to secure a good position.

Multiple Traumatic Hemorrhages of the Liver Associated with Multiple Pulmonary Emboli of Liver Cells and Giant Cells Resembling Bone-Marrow Cells.—By Alfred Scott Warthin.

New York Medical Journal, September 15, 1900.

The Treatment of Tuberculous and Purulent Joints with Large Glass Speculum Drainage and Pure Carbolic Acid; with Report of Seventy Cases.—A. M. Phelps summarizes his results in the following statements: in the seventy cases there have been twenty excisions. In all the other cases the joints have been freely opened and portions of bone and cartilage which were found dead in the joint removed in nearly every one. In fifteen of the cases the head of the bone was found separated from the neck and lying as a sequestrum in the joint. In thirty cases the disease was confined to the acetabulum, with some secondary infection of the neck of the bone. In twelve cases the abscess had burrowed into the iliac fossa, necessitating an operation there. In forty cases the capsule had ruptured anteriorly into the iliac muscle, finding its way into the iliac fossa or into Scarpa's triangle. In two cases the abscess had gone through the thigh from Scarpa's triangle and had appeared in the gluteal fold posteriorly. Fifteen patients who had been subjected to excision of the hip left the hospital with their splints on four weeks from the day

of the excision, three left the hospital at the end of two months; two required subsequent operations, and one of these left the hospital at the end of four months, and the other, with extensive disease of the pelvis, has been in the hospital five months and will be discharged within a week or two; and three more are reported as having been operated on last week. In all the cases requiring excisions or extensive bone operations the patients were discharged from the hospital in an average of three weeks from the time of the operation, wearing hip braces or using crutches. The wounds were firmly closed in all the cases, except those reported as not closed, and remain so.

The Lingual Tonsil.—Robert Levy says that depending upon the prominence with which certain individual symptoms exist, one may class these cases into: (1) those of simple discomfort; (2) those of severe cough; (3) those of vocal distress; (4) those of respiratory distress; (5) those of distress in swallowing; (6) hemorrhagic cases. The symptoms referable to these various conditions are considered in detail. He offers a word of caution and warning to the effect that many individuals present comparatively large lingual tonsils, but that they are not responsible for any symptom, and, moreover, it is not always safe to conclude that because certain peculiar nervous symptoms are relieved by the application of the galvano-cautery to the base of the tongue, these symptoms were the direct results of disease at this situation. In certain highly neurotic patients the effect of counter irritation or the profound mental impression made by rather severe and, to some, formidable local treatment, cannot be excluded.

Generalized Tuberculous Lymphadenitis, with the Clinical and Anatomical Picture of Pseudoleukæmia: the Study of a Case.—By T. R. Crowder.

A Consideration of the Statistics of Operations for the Relief of Malignant Disease of the Larynx.—By D. Bryson Delavan.

Were these Unusual Cases of Partial Paralysis of the Vocal Bands Caused by Over-Use of the Telephone?—By Clarence C. Rice.

The Philadelphia Medical Journal, September 15, 1900.

Mental Disturbances after Operations upon the Eye.—William Campbell Posey reports twenty-four cases in which delirium followed various operations upon the eye. The delirium was of the same character in all, beginning with mild restlessness and developing into active delirium with hallucinations and ideas of persecution, but passing rapidly under control by the proper administration of narcotics; permanent affection of the brain was not remarked in a single instance. The writer is convinced from a critical study of the subject that the cause of this delirium is largely psychic, and he agrees with Parinaud that it is due to the preoccupation upon the part of the patients prior to and after the operation; this is still further favored by the constraint of the supine position and the unusual stillness of the surroundings. Treatment consists in the free and repeated administration of chloral and the bromides. There is no reason to discontinue the employment of atropine. Constant oversight and judicious and tactful nursing are most essential.

Resolution as an Etiological Factor in Post-critical Temperature of Lobar Pneumonia in Children.—By William N. Fisher.

Post-diphtheric Paralysis of Both External Recti Muscles; Report of a Case.—By Harry Friedenwald.

A Few Cases of Diphtheria and What They Taught Me.—By John Leverett.

Inversion of Uterus; Uterine Inertia; Short Cord.—By Edward K. Bacon.

Neurasthenia.—By J. T. Eskridge.

Journal of the American Medical Ass'n, Sept. 15, 1900.

Some Facts Medical and Surgical about Appendicitis.—J. H. Carstens sums up his conclusions as follows: (1) It ought to be a general rule to operate on every case of appendicitis as soon as the diagnosis is made, but when it is a first attack and mild, or no proper facilities are at hand for operation or subsequent care of the patient, it is often good policy to wait and watch the case. (2) In cases of second or subsequent attacks, however, the patient should be sent to a hospital, even if it is at quite a distance—unless good facilities can be had at home—and an operation promptly performed. (3) Statistics of cases operated on as they come along, good, bad, and indifferent, by experienced surgeons, give a mortality of only eight per cent. (4) Statistics collected by general practitioners who are able and up to date, and who advocate surgical interference, show that medically treated cases have a death rate of at least fifteen to twenty per cent.; that at least sixty per cent. have recurrences; while in the cases operated on the patients are absolutely cured.

Cutaneous Manifestations in Diabetes Mellitus.—S. Sherwell gives the following list, made out in the order of relative frequency. (1) Xeroderma, or a condition of dry skin; (2) pruritus, without any, or at least any noteworthy, objective lesions, the genital regions in both sexes apparently suffering most; (3) eczemas, partly neurotic, at other times catarrhal; (4) furunculosis, often general in character, but sometimes regional; (5) conditions of erysipelatous manifestations and gangrene; (6) xanthoma diabeticorum, a disease accompanied by formation of xanthomatous new growths, often in immense quantities, and more particularly over extensor surfaces of body and limbs; (7) possibly, the recently recognized and not much investigated "blastomycetic dermatitis," in which tumors looking like verrucous lupus, or the so-called "tuberculosis verrucosa cutis," become fungoid in character, and on microscopical examination are found to be filled with the fungi of saccharine fermentation; (8) dermatitis herpetiformis—Duhring's disease.

Diabetes Mellitus in Children.—Henry Dwight Chapin gives the following conclusions as to this disease in children: First, it is exceedingly rare. Second, it is a disease exceedingly fatal to young children, although this writer cannot tell why. In the two cases he reports there was no evidence of assimilative disturbance, and the children had been in a state of good nutrition. Third, this disease in children is accompanied by very rapid emaciation. The author believes that whenever a child is brought to the physician with a rapid atrophy, he should examine the urine for sugar.

Improved Lantern for Testing Color Perception.—By Charles H. Williams.

Improved Method of Testing Color Perception.—By William Thomson.

The Relative Value of Homatropine as a Cycloplegic: a Clinical Study.—By E. C. Ellett.

British Medical Journal, September 8, 1900.

Yellow-Fever Expedition of the Liverpool School of Tropical Medicine.—In these preliminary notes Herbert E. Durham and Walter Myers say it appears certain that neither the handling of or contact with yellow-fever patients nor the performance of necropsies is capable *per se* of conveying the disease to non-immunes. It also appears probable that general ships' cargoes and the fomites of patients are not directly infective, although the evidence as to this point is not conclusive. It seems to be fairly definitely established that a patient may become a danger by "infecting the house" in which he is placed. Given that a house is "infected," a visit by a non-immune person entails considerable risk of contracting the malady. Complete and absolute immunity is not acquired by a single attack, though second attacks are usually comparatively mild, or at any rate of a recoverable type. The statement so frequently repeated in text-books, to the effect that colored people and natives never suffer from the disease, seems not to be true. The writers saw one negro during the course of a typical attack, and although Cubans and Cuban doctors assert that the Cuban system is incapable of contracting yellow fever, they are known to suffer from a disease called "borras" and also from "pernicious malarial fever," the symptomatology and pathological anatomy of which are very suggestive of yellow fever. In "borras" there is sometimes black vomit with suppression of urine, and the lesions of yellow fever are said to be present in fatal cases.

On the Treatment of Blisters.—Arthur H. Ward advocates the following: The blister is incised and the raised epidermis cut completely away with sharp scissors; no overlapping fragment beneath which microbes might develop is left. The surface is then carefully dried and painted with several layers of salicylated collodion. A circular piece of soft linen is cut rather larger than the exposed surface, and this is plastered on with more collodion, which is worked well into the meshes of the material. Several more coats of collodion are put over all. This makes a strong protection to the abraded surface, and the patient can at once walk with comfort. If a blister has been neglected and is inflamed it should be treated with antiseptic lotions for a day or two before the method is applied.

Hay Fever.—George H. R. Dabbs says that not for many years has he been free from hay-fever symptoms until this summer. This immunity he thinks may possibly be due to the use of an ointment of the liquor carbonis detergens as strong as it can be made, with benzoated lard, and not too thick to be easily painted on the inside of the nostrils and snuffed up well from the loaded brush.

The Lancet, September 8, 1900.

Expectancy of Life in Cases of Cancer of the Breast.—Arthur E. Barker, in a clinical lecture, after dwelling on the present methods of radical and extensive removal of not only the breast but surrounding parts, goes into figures and gives statistical tables grouped as follows: Group I. includes cases of patients known to have died long after excision, presumably from recurrence, though one certainly died from calculous pyelitis without recurrence, and possibly others. Fifty-two patients have died at intervals ranging from two months to over seven years. Group II. comprises cases of excision of the breast in which the patients were known to be alive at the intervals given, grouped with those alive and without recurrence respectively ten years and one month, one year and seven months, and one year and two months when last heard of more than a year ago. Of these twenty were known to be alive at the intervals given, and of these fifteen are, or were, alive over three years. Group III. includes cases of patients known to have died, taken together with those still alive and examined as to duration of life. From this it will be seen that sixteen per cent. lived over five years and 33.7 per cent. over three years. These figures appear to justify the hope that the expectancy of life is improving as time goes on. It is clear that over thirty-three per cent. of patients live more than three years after the operation, which has suggested to some surgeons that such cases should be regarded as permanent cures. But some of the cases (26.9 per cent.) have resulted fatally, most likely from recurrence, in all but one after an interval of immunity of over three years, so that such a presumption is unwarranted. Another interesting point comes out from this analysis—namely, that only seven suffered from local recurrence. Those in whom the disease has returned have shown it in internal parts. This is another good feature of the modern operations, local recurrence being most depressing and painful, while internal generalization is often not so. The entire set of figures is based on one hundred consecutive cases.

Some Remarks upon the Treatment of Heart Disease, with Special Reference to the "Hill Heart."—H. J. Campbell speaks of the physics of the Nauheim system, calling attention to the fact that while it is most excellent in its results, and that while Oertel's system of graduated walking exercises is of service, both presuppose a heart which has muscle substance capable of either exerting more force under increased stimulation, or increasing its power on contraction as the result of its hypertrophy, or at least of recovering itself if nutrition is favorable. The difficult cases are those in which the heart muscle is so degenerated that it is unable to react to the means employed for its relief. Here an endeavor must be made to lessen the work the heart has to do. Another set of cases is found in which the heart acts very well under normal circumstances, but does badly under any sudden strain. Here there are alarming and dangerous attacks. These may cause only distress, dyspnœa, or anginal pain, or they may induce syncope, or even lead to seizures of an epileptiform or apoplectiform character, and may, and not infrequently do, terminate in almost sudden death. Illustrative histories are given of the different varieties of cases. As to therapy, the author lays stress on balneology and gymnastics, which, however, must be interdicted in any advanced stage of arteriosclerosis.

Case of Diffuse Suppurative Peritonitis from Gangrene of the Appendix; Laparotomy; Recovery.—H. A. Duffet gives some statistics bearing on the subject, and details the history of a boy aged fourteen years treated for acute pain and abdominal distention, with vomiting and constipation. The symptoms of peritonitis gradually developed, and the abdomen was opened by a four-inch incision below the umbilicus. Free offensive pus was found in the pelvis, with a gangrenous appendix. No concretion was seen. The patient did well for five days, when the temperature rose with symptoms suggesting a recrudescence of the peritonitis. A fresh abdominal incision disclosed a small pus pocket in the right iliac fossa. Thereafter the boy did well, though healing of the incisions was slow.

A Note on Pathology and Treatment of Gastric Ulcer.—W. Stuart-Low believes that gastric ulcer is favored by the deficient secretion of the glands of the alimentary tract, more especially the mucous secretion. He consequently orders in such cases mucin in ten-grain doses. It is prepared in cachets from animal bile and is given in doses of gr. x. along with an equal amount of sodium bicarbonate just before meals, with a little water. Diet and other measures are as usual.

The Removal of Septic Effusions from the Cavities of the Human Body.—Edward Armitage advocates the use of mercurial ointment, believing that this time-honored remedy has fallen into an undeserved disuse.

Some Aspects of Biology.—Presidential address by Sir William Turner before the British Association for the Advancement of Science.

Prussic Acid in Sweet Cassava.—By Professor Carmody.

Berliner klinische Wochenschrift, August 27, 1900.

The Treatment of Antral Empyema.—Max Halle advocates the procedure followed in Krause's clinic in Berlin. The antrum is opened by a trocar in the interior nasal meatus and its contents are evacuated by syringing through the opening thus made, out through the natural opening in the middle meatus. By means of the syringe an air douche is driven through the antrum and it is again syringed. The air douching is again resumed until the interior of the cavity has been made fairly dry. Iodoform is then freely insufflated into it. No packing whatever is used. Halle claims that this plan of treatment (the dry method) is not difficult, can be done without narcosis, avoids all communication with the mouth, relieves the patient from the disagreeable taste of iodoform packing, as is so often necessary in operations through the canine fossa, and produces healing in less time than by other methods.

The Especial Danger of Acute Purulent Middle-Ear Inflammations in Advanced Life.—Heine gives a study of sixty-three fatal cases of meningitis following middle-ear trouble, in which the antecedent history was one of acute or subacute ear inflammation in thirty-one, and of chronic trouble in thirty-two. Of the latter only five cases occurred in patients over forty years old, but of the former no less than sixteen fell in this category. He is disposed to explain this fact by the late disclosure of meningeal trouble in this last-named class, a result due in turn to the fact that in later years the bone surrounding the inflammatory area becomes hardened and even eburnated so that external escape of the inflammatory products is rendered difficult. Necessity for operation is consequently not so evident, and meningeal infection occurs before the true condition is recognized.

Affections of the Nose in their Relations to General Affections.—A. Seifert reviews familiar ground, calling special attention to the fact that various cardiac neuroses are dependent on intranasal conditions. Chlorotic girls often suffer from a dryness of the nares, and in the various blood diseases, so-called, bleeding from the nares is a frequent occurrence. The nose is often the channel of entrance of the infective agents in many contagious diseases, such as scarlatina, diphtheria, tetanus, etc. The same observation holds true with reference to the chronic infectious maladies such as tuberculosis and lupus. The article contains nothing new.

Kidney Operations in Cases in which One Kidney is Absent or Diseased.—By Mankiewicz.

Deutsche medicinische Wochenschrift, August 30, 1900.

Queirolo's Method of Determining the Stomach Boundaries.—Edel and Volhard have experimented with this method to determine its accuracy and utility. The apparatus devised by Queirolo and Landi consists of a stomach tube, the lower extremity of which is closed by a distensible balloon, while the free end is provided with two pieces of tubing. One of these is connected to a Marey's tambour, while the other is simply closed by a stop-cock. After in-

troduction of the tube the balloon is lightly inflated through the open tube, and the membranes of the tambour are thus made tense. On now gently percussing the abdomen and watching the index of the registering apparatus, an excursion of the lever is observed as soon as the stomach is reached, while it stays at rest so long as only the intestine is being percussed. The inventor claims that by this means much greater exactness of diagnosis in stomach diseases will be made possible, and that our ideas of the normal limits may have to undergo change. In order to test the method the authors first determined and marked out the gastric boundaries by means of the instrument, and then inflated the stomach with carbonic-acid gas and repeated the percussion. It was found that the results of the two methods were identical, though some skill is necessary in interpreting the movements of the registering index. For routine use the instrument offers no advantages over the far simpler and equally accurate inflation with air or carbonic-acid gas, and gives no information not obtainable by the customary methods of diagnosis.

A Myxomatous Endothelioma of the Soft Palate.—H. Cordes reports a case of this rather unusual new growth and discusses its pathological aspects. Only one hundred and thirty-eight cases of tumor in this situation are to be found mentioned in the literature, and of these nearly one-half are either sarcoma, carcinoma, or adenoma, only four being endotheliomata. These tumors originate in the endothelial lining of the tissue-clefts or lymph and blood-vessels, and are characterized by a strong tendency to degenerative changes. Colloid, hyaline, or myxomatous metamorphosis nearly always is found to a greater or less extent, which greatly enhances the difficulties of a microscopical diagnosis. The clinical manifestations are slight, and after years of growth the tumor may be discovered only by accident. Even when of large size these tumors are painless and give rise only to mechanical symptoms, dysphagia, aphasia, or dyspnœa through pressure on the epiglottis. In general they are non-malignant in type, having no tendency to the formation of metastases, and when removed in season do not recur.

Can Roentgen-Ray Transillumination Differentiate Aortic Aneurism from Intrathoracic Tumor?—E. Gebauer answers this question in the negative, and in illustration cites a case in which the fluoroscopic diagnosis and post-mortem findings did not agree. The symptomatology and physical signs gave evidence which might be interpreted as indicating either aneurism of the aorta, pulmonary phthisis with considerable glandular infiltration, or an intrathoracic new growth. On *x*-ray examination a mass was made out just above the heart and exhibiting very distinct pulsation, so that the diagnosis of aneurism seemed assured. The necropsy revealed a carcinomatous growth of the œsophagus, which had spread to the lungs and broken down in places; the pulsation observed was apparently purely transmitted.

Hæmatological Investigations.—By E. Becker.

Münchener medicinische Wochenschrift, August 28, 1900.

Immunity.—Buchner divides the general subject into two headings, natural immunity, or preferably resistance, and specific immunity either acquired by chance or produced experimentally. Regarding the former our views are changing somewhat, and it is being recognized that in addition to the phagocytic power of the leucocytes they possess at least one other property of use in fortifying the organism. This is the faculty of producing alexins, which by many observers are supposed to appear only on the death of the cells themselves. The author differs from this view, however, and emphatically affirms that the leucocyte is not the easily destructible thing it is usually considered, and that even during its life if the proper stimulus be present alexin secretion can take place. We can no longer rely on the microscope alone in our study of this subject, and advance is to be made along chemical rather than histological lines. In discussing the subject of specific immunity the greatest difficulties are encountered owing to the hopelessly confused state of the terminology. A simple and logical nomenclature would be to make the two groups of alexins and anti-bodies, and, keeping the general prefix anti-, to subdivide the latter into antihæmatins, antitoxins, etc., according to their specific nature.

Traumatic Tetanus Complicated by Intestinal Obstruction.—Krey and Sarauw were called to treat a boy twelve years old giving the typical clinical picture of intestinal obstruction. Soon after coming under observation characteristic convulsions and rigidity set in, which were ascribed to tetanic infection of a scalp wound. A laparotomy revealed the cause of obstruction as an intussusception of the small intestine, which was readily reduced and the abdominal symptoms were relieved. Tetanus antitoxin was not available, but under symptomatic treatment the patient did well and was discharged cured in a month. No definite connection between the tetanus and the intestinal condition could be established.

Observations on the Prognostic Significance of the Diazo Reaction in Tuberculosis.—F. Becker finds that a positive diazo reaction does not always indicate a bad prognosis in phthisis. Temporary and unimportant complications may cause the phenomenon quite independently of the main trouble. If the reaction appears in cases in which it is usually absent, a complication of infectious nature is to be looked for. In some cases the reaction is doubtful, and a positive interpretation cannot be made. Usually the appearance of a green precipitate after the solution has stood twenty-four hours is taken to indicate a positive reaction, but sometimes this coloration is observed also in negative cases.

The Treatment of Tetanus Uteri.—Jacob describes a case of transverse presentation in which version was accomplished with great difficulty, and the child was extracted as far as the head. The uterus spasmodically contracted on this, but finally relaxed under the prolonged application of hot compresses to the abdomen. The delivery of the head was followed by copious hemorrhage and atony of the uterus. This was controlled by traction on the anterior lip of the cervix with Museux's forceps, massage, and ergot. Attempts at expression of the placenta by Credé's method failed, and its removal was not effected till the following day, when it was extracted by digital curettage.

Antitoxin Treatment of Tetanus.—Reuter's case forms an interesting pendant to the one reported by Krey and Sarauw, in which a severe tetanic infection was recovered from without any specific treatment. In the present instance death resulted though antitoxin was promptly given, and in spite of the fact that the slow onset of the symptoms made the case seem a favorable one for treatment. Nevertheless the convulsive seizures steadily increased in severity and reached their acme forty-four hours after the first injection, and death followed sixteen hours later.

A Case of Gonorrhœal Metastases in the Joints and Skin Secondary to Blennorrhœa Neonatorum.—Paulsen says that although joint affections of gonorrhœal etiology are frequent enough after genital infection, it is very rare for metastases to follow specific ophthalmia. He reports a case in which both knees and one wrist of an infant ten days old became inflamed secondarily to the eye disease. Gonococci were found in the joint fluid and also in the secretion obtained from vesicles forming a well-marked eruption on the face, body, and limbs.

Bulletin of the Johns Hopkins Hospital, September, 1900.

The Distribution of Connective Tissue in New Growths.—W. C. White concludes that elastic fibres are frequently present in new growths, in the stroma, among the cells, around the blood-vessels, and in breast tumors around the lactiferous ducts which have been included and invaded by the growth. They are usually in connection with pre-existing elastic tissue elements in the original tissue in which the tumor has grown. New formation probably occurs. Sarcomata present a large increase in connective tissue and possess a fine intercellular network similar in structure to the reticulum present in normal glandular tissue. Carcinomata possess a stroma of white fibrous tissue outlining the cell spaces, but have no intercellular network. The digestion methods present a possible means of diagnosis between carcinomata and sarcomata in doubtful cases. Uterine myomata have a large amount of both white fibrous and reticular connective tissue, possessing a connective-tissue capsule for each muscle-cell; and they would be more correctly termed fibromyomata.

A Contribution to the Study of Malignant Tumors Arising in Congenital Moles.—R. H. Whitehead says that among the widely differing opinions one finds it difficult to reach a definite conclusion as to the nature of the nævus cells, but the pictures of Scheuber and of Gilchrist are suggestive, and one may be permitted to hold the view that in some moles, at least, the groups of cells are modified epithelial cells of epidermal origin. Should a tumor spring from such cells, we should naturally expect it to follow the type of carcinoma. This expectation, however, is not always realized. Nine tumors of this class, which the author has been able to examine, had that histological structure which most pathologists have agreed to call alveolar sarcoma, and were so pronounced by competent observers. The author reports two cases in which the tumors

springing from congenital moles represent the same processes as those going on in the melanotic tumors, with the exception that they totally lack true melanotic pigment.

On the Histology of the Islands of Langerhans of the Pancreas.—Eugene L. Opie reaches the following conclusions: (1) The islands of Langerhans are composed of cells having the same origin as those of the glandular acini, but forming structures which are independent of the secreting apparatus and in intimate relation with the vascular system. (2) In the splenic end of the cat's pancreas they have a definite position within the lobule, each of which contains one of these structures. (3) In the human pancreas they are more numerous in the splenic extremity or tail than elsewhere. (4) Prolonged stimulation of the gland does not, as claimed by Lewaschew, transform groups of acini into islands of Langerhans.

Typhoid Fever in Childhood.—A. D. Blackader analyzes the features of one hundred consecutive cases occurring in children under fifteen years of age. Concerning the use of the bath he finds that the nervous system of the child responds more quickly and energetically to the cool bath than does that of the adult, and the amount of response has to some extent an inverse proportion to the age. It is therefore unnecessary and undesirable that as low temperature should be employed in the case of a young child as in the case of an adult. He believes it to be a great shock to a young child to plunge it at the outset into a bath of 68° or even 75° F.; while a bath of 90° cooled to 85 and repeated regularly for the first few days of the attack gives rise to neither resistance nor signs of shock or collapse on the part of the child. Later on in the disease lower temperatures may be employed if found necessary. Even after the pyrexia falls below 102° F., he believes that the regular use of the cool bath once or twice a day strengthens the heart action and tends to a more rapid convalescence.

General Subcutaneous Emphysema.—A. C. Cotton reports the case of a child aged seven and a half years who, during hard coughing incident to a severe bronchitis, developed a ridge over the right clavicle from which point extension took place in all directions. Examination of the surface showed great distention about the neck and chest, completely obliterating clavicular depressions, and extending downward over the trunk, especially in the dorso-lumbar region along each side of the spine. Pressure elicited distinct crepitation and left no pitting. Respirations were shallow and rapid (50 per minute); the pulse was rapid and barely perceptible; temperature 102° F. During the six subsequent days of life, infiltration of the subcutaneous tissue extended, involving both upper and lower extremities with the exception of palms and soles, the skin becoming tense and shiny. The paroxysms of coughing increased in frequency, being nearly continuous the last twenty-four hours. There were increasing dyspnœa and deepening cyanosis.

Two Cases of Fatal Lead Poisoning.—Allen Baines mentions as a characteristic symptom of this condition in childhood a very pronounced dark blue circle about the anus, more marked in his two cases from the fact that the children were of fair complexion. The meals of the family of his patients were cooked with firewood procured from the staves of old barrels which had contained white lead, so that the fumes of lead not only entered the food but permeated the atmosphere. The children affected were brothers. Urine examination showed the presence of lead. In both convulsions were a prominent feature.

Exclusive Soup Diet and Rectal Irrigation in Typhoid Fever.—By A. Seibert.

Annals of Surgery, September, 1900.

Massage in the Treatment of Recent Peri-Articular Fractures.—G. Woolsey reviews the arguments advanced in favor of this form of treating fractures, stating that the claim is made that a certain amount of motion is favorable to the repair of bone, and that massage, in addition to furnishing this, prevents atrophy of the muscles, reduces swelling, and restores the circulation. In this and other less clearly known ways it causes the repair of bone to be rapid and, in combination with passive motion, prevents the stiffness of the neighboring joints. He has followed this plan in Pott's cases, in fracture of the patella, obtaining in one case firm union and almost perfect motion in twenty-four days, and in fractures about the elbow-joint. He sees no advantage in discarding splints in the early period of the treatment. Their use gives confidence to the patient and the surgeon alike, and a sense of security that no displacement is likely to occur. Particular attention should be paid to the position of the limb by carefully reducing any deformity, and keeping it reduced during massage and between the periods of massage, when the limb is in a splint. If this is not possible from the outset, after a preliminary massage, plaster should be applied, and kept on for from eight to fourteen days, and then massage commenced. The result in these cases is better as far as position is concerned, equally good functionally, and nearly, if not quite, as quickly obtained as when massage is employed from the first. If, again, after massaging for some time, the position is found to be imperfect, or if, after three weeks, quite firm union has not taken place, Woolsey believes in using a plaster splint for eight to fourteen days, though the functional result is thereby delayed. The application of massage and passive motion is easy. It relieves pain and swelling, hastens callus formation and solidification, and prevents atrophy of the muscles and stiffness of the joints and tendons.

The Ileo-Cæcal Orifice and its Bearing on Chronic Constipation; with Report of Two Cases Relieved by Operation.—W. J. Mayo believes that a narrowing of the ileo-cæcal valve is the cause of certain cases of obstinate constipation. In a case requiring removal of the appendix, he noticed that the calibre at this point of the bowel was markedly reduced, having almost the appearance of constriction by a string. There was no evidence of previous disease or ulceration. Obstinate constipation of the patient led the doctor to expose the valve and make an incision two and a half inches in length at right angles to the ileo-cæcal junction, having its centre at that point, and so to suture the wound transversely as considerably to increase the calibre of the valvular opening. Recovery was uneventful, and the constipation practically disappeared. The writer advances the following theory as explaining the good results obtained: The secretions in the small bowel are alkaline, in the large bowel slightly acid, and in the production of this change gases are evolved which materially aid the passage of fecal matter along the large bowel. The thinness of the muscular coat of the large bowel and its sacculation make it evident that flatus is a necessary adjunct to fecal progress. It becomes a question, also, as to whether or not the greater amount of absorption which takes place in the small bowel under such circumstances leaves the contents, when passed, in a condition less favorable to stimulate the peristalsis and production of gases in the large bowel.

The Results of Castration and Vasectomy in Hypertrophy of the Prostate Gland.—This is a statistical article by A. C. Wood, who has collected the records of all ascertainable cases since the date of the papers on the same topic by White and Cabot. Wood has gathered the records of one hundred and fifty-nine additional cases of castration and of one hundred and ninety-three additional cases of vasectomy. In the former series there were thirteen deaths from sepsis due to pyuria, pyelonephritis, suppression, emphysematous phlegmon, pneumonia, exhaustion, etc. The results in general were as favorable as in the previously reported cases: of the vasectomies, general improvement followed the operation in sixty-seven per cent. of the cases. There were thirteen deaths, from about the same general run of causes as above stated. Dr. Wood's article is a most valuable contribution to the literature of this subject.

On the Influence of Anæsthesia on the Effect Produced on the Circulation and Respiration by Irritation of a Sensory Nerve.—S. P. Kramer notes that in experiments on dogs there was in each instance a stage of narcotization at which the irritation of the central end of the crural nerve produced a fall in blood-pressure. The conclusion may be drawn from these experiments that severe vasomotor shock is more liable to follow operations done under partial anæsthesia than such as are done under complete insensibility.

Excision of the Wrist by a Modification of Mynter's Method.—By W. J. Taylor.

Scottish Medical and Surgical Journal, September, 1900.

A Case of Erythema Induratum Scrofulosorum.—The patient of D. S. Doughty was a girl aged twenty years with pulmonary tuberculosis, who did well on open-air treatment with full feeding and guaiacol carbonate and creosote internally. Seen again a few months later, she was found in bed complaining of aching all over the body but especially in her legs, on which, she said, there were spots. Her temperature was 100.4 F.; her pulse somewhat quicker than usual. A careful examination of her chest failed to reveal any return of the former mischief. There was no cough and no expectoration could be got for examination. On the lower two-thirds of the calves of her legs there were several nodules, more numerous on the left leg than on the right. These nodules were of various sizes and mostly of a purple violet color, some darker than others. In one or two of them there was a small hole in the centre from which exuded a slight discharge. Some which were not visible to the eye could be felt under the skin. Doughty's first impression was that the lesion was syphilitic. Sodium salicylate was given, followed by the iodide. The latter gave no evident benefit. The case ran an indolent course, the nodules growing less in size and color but not entirely disappearing as long as the case was under observation.

On Transfusion.—T. Annandale concludes as follows regarding this therapeutic measure: (1) It may be a valuable aid in saving life in the case of patients suffering from serious loss of blood, provided they show no signs of reaction after the ordinary means have been carefully tried. (2) The best form of transfusion for ordinary use is the injection of human blood mixed with a solution of phosphate of sodium, and kept at a proper temperature, so as to prevent clotting. (3) If the former method cannot be properly carried out, the injection into a vein of saline solution (chloride of sodium) is the next best procedure. Both of these procedures must be carried out with the most strict and careful antiseptic precautions. (4) Intra-peritoneal injections of warm water, or of warm saline solutions, are most likely to be useful in cases in which the abdomen has already been opened, for without an opening there is always a risk of injuring the intestines or other internal organs with the trocar and cannula. (5) Injections of warm water or of warm saline solutions into the rectum, or into the cellular tissues, is a safe and simple procedure, which may be usefully employed in any sudden emergency.

The Importance of Accurate and Detailed Diagnosis in Abdominal Cases.—Three cases illustrating the importance of this proposition are described by William Russell. Their titles are respectively: Gastric Ulcer with Appendicitis simulating Perforating Gastric Ulcer; Dyspepsia with Chronic Œsophageal Ulcer simulating Chronic Gastric Ulcer; Calculus in the Lower Extremity of the Ureter simulating Appendicitis.

Inflammation of the Uterine Appendages.—A clinical lecture by A. H. Freeland Barbour.

A Case of Cæsarean Section followed by Subperitoneal Hysterectomy.—By N. T. Brewis.

The Edinburgh Medical Journal, September, 1900.

Can the Period of Infectiveness of Diphtheria be Shortened and its Tendency to Spread Diminished?—William Ewart urges thorough disinfection of the nasal cavities and naso-pharynx in all cases of diphtheria, before children are allowed to return to the companionship of others. Whatever the method adopted, it should be applied early during the attack, and perseveringly and continuously during the period of convalescence. At St. George's Hospital it is the author's practice to have all cases of diphtheria under his care receive local treatment for the nose and naso-pharynx by the introduction of carbolized oil twice daily throughout their stay at the hospital, with a view not only to relieve local discomfort or lesions, and to prevent the spread of the latter, but also to insure, if possible, in all cases a gradual cleansing and disinfection of the entire mucous surface, by the spreading upward of the oil, which is dropped in with a camel's-hair brush, with the patient's head thrown back.

Jacksonian Epilepsy due to Cerebral Abscess following upon Typhoid Fever.—Andrew Cassels Brown reports a case which is of interest: (1) Because it followed apparently upon an attack of typhoid fever. Presumably the same pyogenic organisms gained access to the system by means of the intestinal ulcerations and were deposited in the brain, becoming foci for the abscess which resulted. (2) Because of the position of the abscess. It was situated in the Rolandic area of the right side, extending practically all over the ascending parietal and ascending frontal convolutions, involving the upper, middle, and lower thirds of the motor area. (3) Because of the difficulty of making a correct diagnosis of the exact nature of the lesion. Abscess, in fact, was excluded, and the diagnosis of a rapidly growing tumor was made. (4) Operation was performed, and was entirely successful. The patient has entirely recovered the use of her leg, and to a certain extent of her arm. She is well, and much pleased with the results of the treatment.

Clinical Lectures on Circulatory Disorders: II. The Cause of the Presystolic Murmur.—By John Orr.

A Contribution to the Mechanism of Articulate Speech.—By S. W. Carruthers.

Two Cases of Poisoning by Cannabis Indica.—By James Foulis.

Norsk Magazin for Laegevidenskaben, September, 1900.

A Case of Intoxication from Camphorated Naphthol.—Sinding-Larsen reports the case of a girl aged twelve years, suffering from white tumor of the knee. An injection of 5 c.c. of camphorated naphthol was made into the articulation on February 8th, with no bad results. Eight days later another injection was made with some difficulty, owing to beginning obliteration of the joint. Only 4 c.c. was administered, when suddenly the patient had epileptiform convulsions, delirium, and symptoms of cerebral weakness (weak pulse, cyanosis, pulmonary œdema). The expired breath two minutes after the injection had a strong odor of camphor. The cramps and the delirium ceased in about ten minutes, but the symptoms of cerebral weakness continued for twenty-four hours, and did not entirely disappear for several days. The author advises caution in the use of the remedy, and believes that an injection should not be forced when obstacles are met with, as in cases of obliterated articulations and sclerosed glands.

The Etiology of Chorea Minor.—Theodor Frölich reports forty-seven cases in children from three to sixteen years old. In twenty-four of these there was a family history of rheumatism or of psychical trouble. Fifteen of the patients had had acute rheumatism. In sixteen the chorea was ushered in or accompanied by febrile symptoms with angina, articular affections, or erythema nodosum. These sixteen cases the author considers to be infections. In four patients the chorea followed other infectious diseases—scarlatina, influenza, and epidemic muscular rheumatism. In twelve cases there was no previous infection, but three of them had cardiac lesions. On the whole, the author holds that in 80.85 per cent. of the cases infection was proved, and not proved in 19.15 per cent.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CLIMATIC FREAKS—BUBONIC PLAGUE IN GLASGOW—EUTHANASIA ADVOCATED BY "A PHYSICIAN"—THE WAR HOSPITALS—MR. BURDETT-COUTTS CONTRADICTED—THE COMMISSION.

LONDON, August 24, 1900.

AGAIN we have been having a cold snap while reading telegrams of your sufferings under another heat-wave. The thermometer marking barely 60° F. in August made us feel that autumn if not winter had really set in. Last year at the same time it was in the eighties. On Monday and Tuesday it was quite curious to see men going about in overcoats with collars turned up and ladies in sealskins and muffs. The shops, too, were suddenly transformed, for the windows were dressed with winter garments. Yesterday the rigor had relaxed and the thermometer was in the seventies. But the sky was overcast and we had only forty minutes of clear sunshine. To-day is just the same. The meteorologists are divided as to whether we are entering a period of summer or must first pass through storms.

Glasgow has had a week of anxiety on account of a visit of the plague. A suspicious death occurred in hospital on Monday, and precautions were at once taken, while experiments were being carried out by Professor Muir. The result of these is that to-day the medical officer of health officially announces that the death was caused by plague. One or two other suspicious deaths have occurred. You must not think the last few days have been passed without great activity on the part of the sanitary staff, which has been doubled. It is believed that the outbreak will be

soon stamped out. There are nine suspected cases being carefully watched in the hospital, and fifty-five contacts have been isolated, and one is under observation. The sanitary offices will be kept open night and day. The Paris Pasteur Institute has supplied serum. Quarantine regulations will no doubt affect Glasgow and the Clyde ports, but the Scottish local government board does well to let the truth be known and to second the efforts of sanitary offices to limit the outbreak.

An unfounded report that two ships in Dublin harbor had cases of plague on board gave rise to no little fear on Thursday, when the city was full of visitors to the great horse-show.

In this country suicide is criminal, and persons are often brought before the magistrates for attempting it. Unless under very exceptional circumstances the act is generally regarded as cowardly or disgraceful. Nevertheless, there have never been wanting those who hold it to be justifiable. To assist another in putting an end to his life might lead to a charge of being an accomplice in murder. And yet the question has often been raised, whether the promotion of euthanasia is justifiable by the medical attendant in hopeless cases. Discussion of the point has been started again by a letter in a provincial newspaper signed "A Physician." The writer starts with the assumption that suicide is justifiable—nay, may often be honorable and brave. From this he goes on to argue that as a man has a right to determine his own life, it may be equally right for the physician to assist him in thus ending the sufferings of a patient whose case is hopeless. He would limit this course to those cases in which a rapid but painful end is near, and says he has in a number of cases closed them with chloroform. Religious or moral objections he considers it the business of the sufferer to settle. As to the legal questions he might find it awkward to make this confession to a magistrate, and he does well to write anonymously lest the nearest policeman should fail to appreciate his logic. An academical discussion on the morality of promoting euthanasia may be very well in a medical journal—though, often as the question has been raised, the profession has invariably repudiated the thought of becoming a party to taking or shortening life.

The statements made by Mr. Burdett-Coutts respecting the sick and wounded have been contradicted by another of our consulting surgeons in South Africa, and one, too, who had the opportunity of knowing the facts at Bloemfontein, for he was there at the time covered by Mr. Coutts' letters to *The Times*. This surgeon is Mr. Kendall Franks, who was attached to the army headquarters and accompanied Lord Roberts in his famous march. His testimony is therefore of special value. "I confess," he writes in *The Telegraph*, "I have not been able to locate the especial field hospital described by Mr. Coutts," and then he slyly suggests that perhaps he was "not able to recognize it under the description given by that gentleman." He says, although he has seen overcrowding which was unavoidable, and even men lying on the ground because every available stretcher and bed was occupied, he never saw "in any hospital, field or otherwise, anything resembling the state of affairs described by Mr. Coutts." Mr. Franks further denies that funerals were going on "from morning to night," or that the dead were buried in "unknown crowded graves," as asserted by Mr. Coutts. He says the funerals took place between 2 and 5 P.M., and declares on the authority of the chaplain on the headquarters staff that every body had its own grave, every grave being numbered and the names and numbers registered in the cathedral books. This seems a facer for Mr. Coutts, whose "hysterical word-painting" is once more exposed. Mr. Franks explains why some supplies had to wait—it was because "to supply the troops with proper and sufficient food was the most humane precaution to prevent the spread of disease," and he declares that Lord Roberts should be shielded by the public "from the unfair and carping criticism of an irresponsible itinerant." As to Mr. Coutts' sensational account of the appearance of the troops on arrival at Bloemfontein, Mr. Franks says, "It is not a true picture; it is not exaggerated—it is false."

On the other hand, Mrs. Dick Chamberlain has returned and been interviewed. She says, "Every word that Mr. Burdett-Coutts has said with regard to the dreadful mismanagement of the hospitals is true." Perhaps the common report is correct that Mrs. Dick Chamberlain got hold of Mr. Coutts and through him vented her revenge for being excluded from the hospitals as useless and in the way. If so she would have been well advised to take the hint of Sir A. Milner and return to the excitements of London Society (with a capital S). She told her interviewer that "the army doctors, with but few exceptions, were an inferior class of men." Perhaps some of them will retort that would-be fashionable ladies are an inferior class of women. She further said six cases of drunkenness among them came under her observation, and after coming in contact with the police were sent home in charge of invalids on transports. This statement should be capable of support or otherwise by the police records. I pass by other allegations more difficult of disproof and which will probably be contradicted in due course. So, too, anonymous statements are not worth repeating.

But it appears that there will be evidence submitted to the commission on the defects noticed by competent observers, and we may well await their testimony. The commissioners are quite qualified to weigh the evidence. They have already visited Wynberg and taken the evidence of Colonel Anthonisz, who has been in charge for the last ten months. He denies Mrs. Dick Chamberlain's allegations and attributes them to spite. Professor Dunlop, who was there for six months, has nothing to complain of except excessive red tape.

THE DISCOVERY OF "UREINE," THE PRINCIPAL ORGANIC CONSTITUENT OF URINE.

To the Editor of the Medical Record.

Sir: Kindly permit me to add the following remarks as a postscript to the paper recently published under the above title in the Medical Record:

In order not to weaken the toxic qualities of ureine by exposing it to a high temperature, and also to simplify the method of its isolation, I have found the following procedure to be preferable to the one recommended in my paper: We evaporate the urine at a temperature of 50–55° C. until we are certain that no more evaporation takes place. Then we reduce the temperature of the liquid, if possible to 0° C., and add a convenient quantity of cold absolute alcohol to facilitate filtration. We now separate the urea present by adding pulverized pure oxalic acid, until no further precipitate is formed, and then we filter the alcoholic liquid and evaporate it at 50–55° C. The ureine resulting from this method is sufficiently pure to satisfy all exigencies of clinical-medicine and of physiology, for it is evident that the presence of some saline matter cannot influence the qualities of ureine, and, furthermore, I have convinced myself that the presence or absence of urinary coloring-matters does not alter the symptoms observed in experiments upon animals. If we wish to isolate the ureine for chemical purposes, we continue the above procedure by treating the alcoholic liquid successively with barytes, to remove the sulphates and phosphates, with nitrate of silver to separate the chloride of sodium, and finally with mercuric nitrate to remove the coloring-matters of the urine; it is better not to neutralize subsequently with sodium carbonate. There is one rather important point which I have observed since the preparation of my paper. If we add nitric acid to ureine, a solid, wax-like mass will be formed at once, and this is a fact worth remembering, as otherwise one might think that this solid, wax-like substance was the result of a chemical combination of nitric acid and urea.

William Ovid Moor, M.D.

121 Monte Citorio, Rome, August 12, 1900.

Reviews and Notices.

A Memoir of Henry Jacob Bigelow, A.M., M.D., LL.D., who was Emeritus Professor of Surgery in Harvard University and a member of many home and foreign scientific societies. Boston: Little, Brown & Company. 1900. Together with three volumes, one devoted to orthopædic surgery and medical papers; one to surgical anæsthesia, addresses, and other papers, and one containing: I. The Mechanism of Dislocations and Fracture of the Hip; and, II., Litholapaxy, or Rapid Lithotrity with Evacuation.

The first volume, which contains portraits of Dr. Bigelow, taken in 1841–1872, and an excellent likeness as a frontispiece from a photograph taken in 1888, is devoted to a reproduction of written monographs, addresses, and interviews, contributed by friends and admirers at the time of this distinguished surgeon's death. There is a vigorous biographical memoir by Prof. Oliver Wendell Holmes, and graphic sketches by Professor Fitz, Dr. Cabot, Mr. Lee; reminiscences by Drs. Derby, Beach, and other intimate friends and associates. The miscellaneous papers reproduced in the next volume relate mostly to surgery, and include the more important of Dr. Bigelow's contributions to medical journals, including the Boylston prize dissertation. The interesting and vastly important discovery of surgical anæsthesia, with which the subject of these me-

moirs was closely identified, is gone over here in chronological order by a reproduction of the publications and addresses of Dr. Bigelow bearing upon the questions involved. The first portion of the fourth volume is a reprint of a treatise on the "Mechanism of Dislocations and Fracture of the Hip," for a long time out of print. The second part includes published articles on rapid lithotrity, unmodified except by the author's own annotations. Taken together this set of works makes a fitting tribute to the memory of one who did so much to advance surgical science in various ways and to add to the lustre of American medicine.

Grundriss der orthopädischen Chirurgie für praktische Aerzte und Studierende. Von Dr. Max David, Berlin. Mit 129 Abbildungen. Berlin: S. Karger. 1900.

This is a condensed text-book on orthopædic surgery arranged so as to be especially useful for the student. The illustrations are suitable, though some of them are crude, and the text meets the requirements of the student class, to whom we can recommend the book.

The Year Book of the Nose, Throat, and Ear. Edited by G. P. Head and A. H. Andrews, Professors in the Post-Graduate Medical School of Chicago. Chicago Medical Book Company. 1900.

The scope of this new venture includes a statement of the essential points made in journal articles in the departments covered, which have appeared during the year. It is convenient for reference, and though not exhaustive may be improved in succeeding issues. The work is divided into chapters, and the articles taken at random are referred to the bibliographic list by number and date on which the article appeared. The field is fairly well covered, and the specialist in these branches will find something about most of the advances.

The Criminal: His Personnel and Environment; A Scientific Study. By August Drahms, Resident Chaplain State Prison, San Quentin Prison, California. With an introduction by Cesare Lombroso, Professor of Psychiatry, University of Torino, Italy. New York: The Macmillan Company. 1900.

We find here a result of several years' observation, from the near point of vision, by a practical worker among the class described. The personal and social aspects of the question are chiefly considered. The field is surely large, and no one can successfully maintain that it has been overworked. The present contribution to the moral, social, political, and economic aspects of the condition are of value as an aid in the solution of some of the important questions involved.

International Clinics: A Quarterly of Clinical Lectures and Especially Prepared Articles. Edited by Henry W. Cattell, A.M., M.D., with the collaboration of John Ashhurst, Jr., Charles H. Reed, and James T. Whittaker. With regular correspondents in Montreal, London, Paris, Leipsic, and Vienna. Vols. I. and II. Tenth series. Philadelphia: J. B. Lippincott & Co. 1900.

With the change in editorial management of this well-known quarterly there have come some modifications and alterations in the general construction, and a new staff of assistants has replaced the old. It does not always or of necessity follow that a change is for the best, or that because of a new editor the reader and subscriber are going to benefit. In the present instance, however, one must admit that the captain has taken the wheel as though he were quite familiar with the craft, the waters, and all the reefs and rocks, whether they are down on the chart or not. In selecting contributors for these two volumes the editor has been quite happy, and such names appear as Brieger, Dieulafoy, Flexner, Gautier, Lassar (who has an interesting illustrated lecture on lepra), T. G. Morton, Victor Vaughan, C. J. Aldrich, C. W. Allen, Ballantyne, Bishop, Katzenbach, R. T. Morris, J. B. Murphy, Senator, Skene, Souchon, G. L. Walton, J. C. Wilson, and others equally well known. The literary and scientific quality of the lectures and special articles is of a high order, and the illustrations are well made. The date upon the back has wisely been omitted, since it was more apt to confuse than otherwise. The new editor, who has himself contributed an interesting article to each of these issues, is to be congratulated upon the good impression which the initial volumes cannot fail to make.

The Law in its Relations to Physicians. By Arthur N. Taylor, LL.B., of the New York Bar. New York: D. Appleton & Company. 1900.

In the preface to this useful little handbook the author, implying that there are no similar treatises, says that the need of revealing to physicians their legal relations broke upon him when, casually looking over the pages of a current legal journal, his attention was caught by the case of a physician who had been cast in substantial damages for having violated well-established legal principles. Mr. Taylor, however, has had predecessors. Ordronaux's scholarly lectures on the jurisprudence of medicine, Glenn's excellent manual of the laws affecting medical men, McClellan's "Civil Malpractice," Rogers' book, "The Law and Medical Men," Field's "Medical Guide," are all small books covering more or less Mr. Taylor's limits. More recently Hamilton's "System of Legal Medicine" covers the same field in a special article, and the treatises of Becker and Witthaus and other writers on medical jurisprudence deal with the same topics; and foreign books in the field are not lacking. The lack of a table of cases, which is usually found in law books, renders it difficult to compare Mr. Taylor's work with that of his predecessors as a collection of authorities. Turning the pages we find the familiar cases cited in other books and some of later date. Probably the treatise is not intended to be an exhaustive collection of authorities, for under the important heading, "What Constitutes the Practice of Medicine?" we do not find Underwood *v.* Scott, Wood *v.* Kelly, Harding *v.* People, Alcott *v.* Barber, Musser's Executors *v.* Chase, and other cases cited in the brief for medical prosecutions issued by Treat two years ago; nor do we find State *v.* Paul, holding that one cannot practise under the guise of an assistant, a principle of importance especially under the dental law; for in this State many men have been convicted of practising dentistry unlawfully who have been defended upon the ground that they were assistants of licensed men. We do not find any discussion, by the way, of the very interesting question whether dentistry is or is not a specialty of medicine, although there are a number of reported cases upon that topic which one would expect to find cited under the definition of physician or dentist. Upon the important question whether a physician registered in one county may practise in another without registration, Martino *v.* Kirk is cited, without noting that its rule was based upon the law of 1880, which had been repealed before the case was decided. Wiel *v.* Cowles is cited to the effect that an unlicensed practitioner may be required to disclose confidential communications of a patient; but we do not find the recent holding of Mr. Justice McAdam (McGillicuddy *v.* F. L. & P. Co.) that a licensed physician not legally qualified to practise, because unregistered, may not be compelled to make such disclosure—the privilege being the patient's and not his. There seems to be no note of the many cases decided of late years under excise laws, especially in the West, South, and Southwest, whereby the ability of thirsty gentlemen to evade the law through a physician's prescription is harshly circumscribed. Thus it was held in North Carolina, when a dentist prescribed a pint of whiskey on Sunday for an aching tooth, that a dentist was not a doctor within the meaning of the law—a decision said to be necessary in view of the fact that every normal citizen of North Carolina has thirty-two teeth that might possibly ache at once. There seems to be no mention of the line of cases holding medical men or their patients liable for defamation in making disparaging remarks of one another; nor of the very important topic of medical societies, the obligation to join them, and the rights of members; nor yet of the right of colleges and hospitals to dismiss members of the staff (People *ex rel.* Kelsey *v.* N. Y. P. G. M. S. & H., 29 App. Div. 244). There is no discussion of expert testimony or even of that important question—as to which two rules obtain—whether a physician is bound to testify as an expert for an ordinary witness' fee. For taking a wrong position upon this point Dr. Dixon found himself in contempt of court (Dixon *v.* The People, 168 Illinois, 129). It may be that some of these topics have been touched upon so that one who reads from cover to cover might find them; but we have found no clew to them in the index or table of contents. This only means, however, that the book is not exhaustive and does not entirely supply the place of other treatises the existence of which it does not indicate. It may be, nevertheless, a useful little book for the practitioner, who will bear in mind that any book of the kind can only be for the physician what a "Household Doctor" or pamphlet on "First Aid to the Injured" would be in a lawyer's family. The subject was suggested some time ago by the Medical Record as one which might be profitably included in the curriculum of all medical colleges.

Sixth International Otological Congress, Held in London, August, 1899, under the Presidency of Professor Urban Pritchard. Transactions, edited by E. Cresswell Baber. London: The Southern Publishing Company. 1900.

This somewhat bulky volume of nearly five hundred pages contains the proceedings of the congress above named. It has the peculiarity of presenting the various contributions in the respective languages in which they were delivered; so we find pages in English, French, German and Italian. It is a most admirable example of the ideal volume of

scientific proceedings and of careful editing. The various papers and discussions have been abstracted in many current journals during the past year and call for no special mention here.

The Water Supply of the City of New York. August, 1900.

This large volume contains the result of an inquiry into the conditions relating to the water supply of this city, undertaken by the Merchants' Association of New York. The immediate occasion was the attempt to bind the city to the payment of an immense sum of money to the Ramapo Water Company for water which the city can obtain through its own efforts for a fraction of the amount. The report shows conclusively that there is no danger of a water famine, and that the city can always obtain all the water it needs without having resource to a private company.

Surgical Anatomy. A Treatise on Human Anatomy in its Application to the Practice of Medicine and Surgery. By John B. Deaver, M.D., Surgeon-in-Chief to the German Hospital, Philadelphia. Vol. II. Philadelphia: P. Blakiston's Son & Co. 1900.

The second volume of this really superb work is concerned with the anatomy of the neck, mouth, pharynx, nose, orbit, eyeball, organ of hearing, brain, male perineum, and female perineum. These parts are illustrated by one hundred and seventy large plates and described in three hundred and thirty-seven pages of text. An index of thirty pages makes all this material readily accessible to the inquirer. As an illustration of the thoroughness with which the author treats his subject, we may analyze the section dealing with the organ of hearing. Each division is taken up in turn and described in all its parts from the surface inward; the diseases affecting it, so far as they have any relation to the anatomy, are mentioned, and the anatomical bearings of operations in the neighborhood are touched upon. This fills nineteen pages of text. The plates in this section are twelve in number, as follows: Pinna, intrinsic muscles of pinna, external and middle ear, anterior vein of right tympanum, membrana tympani and its inclination, external view of membrana tympani of left ear, internal view of right tympanum, external view of bony labyrinth, or cochlea and semicircular canals, interior of osseous labyrinth of left internal ear, interior of osseous portion of cochlea, section of osseous portion of cochlea, and diagram of membranous labyrinth. The appearance of the third and concluding volume of Dr. Deaver's unequalled work will be eagerly looked for by those fortunate enough to possess the first two volumes.

A Text-Book of the Medical Treatment of Diseases and Symptoms. By Nestor Tirard, M.D. London, F.R.C.P., Professor of the Principles and Practice of Medicine, King's College, London; Physician to King's College Hospital; Examiner in Materia Medica to the Conjoint Board of England. Adapted to the United States Pharmacopœia by E. Quin Thornton, M.D., Demonstrator of Therapeutics, Pharmacy, and Materia Medica, Jefferson Medical College, Philadelphia. Philadelphia and New York: Lea Brothers & Co. 1900.

It is a curious fact that most medical writers, whether of monographs or of general treatises, while acknowledging that the end of medicine is the prevention and cure of disease, usually devote but little space to therapeutics. It is this neglect of the most important branch of medicine that gives an excuse for works like the one before us. Dr. Tirard takes up the several affections of the circulatory, respiratory, digestive, and nervous systems in turn, and discusses both the general management of these diseases and the various measures adapted to the relief of the special symptoms as they arise. The work is probably not intended to be encyclopedic, yet we think the author has erred somewhat on the side of conservatism in refusing to discuss such methods as the use of carbolic acid in the treatment of tetanus or the serum treatment of pneumonia. Such important affections as epidemic cerebrospinal meningitis, multiple neuritis, beriberi, round ulcer of the duodenum, arteriosclerosis, and ozæna are ignored, or at least are not discoverable on careful perusal of the index and patient search through the body of the book. Certain of the author's recommendations are unsound; as, for example, when he advises, without any qualification whatever, a resort to quinine in the treatment of malarial hæmoglobinuria. Despite these imperfections and omissions, however, the book is one that can be safely recommended, for its blemishes are outweighed by its merits. The author has what medical teachers sometimes lack—common sense and practicality—and his discussion of such common but distressing complaints as dyspepsia and constipation is worthy of all commendation.

Society Reports.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 5, 1900.

The President, Frederick Peterson, M.D., in the Chair.

Exophthalmic Goitre Treated by Intestinal Antiseptics.—Dr. Mary Putnam Jacobi reported a case of this nature. B. D——, aged twenty-two years, was first seen February 8, 1899. She had been well until the age of twenty years, when she began to work in a shop for making infants' clothing. She worked from 8 A.M. until 5 P.M. on buttonholes and feather-stitching. She began to sufier much from constipation, relieved by frequent purgation with licorice powder. At the end of a year menstruation ceased, *i.e.*, in July, 1897. Six months later the eyeballs began to be prominent; at the same time there were flushings of heat all over the body, palpitations, headache, and weakness, tremor of the hands and feet, especially on rising in the morning, and frequent distress in the stomach. In the summer of 1898 constipation was replaced by chronic diarrhœa. In February of this year she had a severe attack of diphtheria, for the treatment of which she entered Mt. Sinai Hospital. On recovery from this the patient felt for a while much better. The thyroid gland was only moderately enlarged and appeared to be slightly larger in the morning, at the same time that the tremor and diarrhœa occurred. There was marked accentuation of both cardiac sounds over the tricuspid, but none at the mitral valve. No cardiac murmurs were audible, but there was a systolic murmur over the carotid artery. The pulse was 120; respiration 24. The sphygmogram was regular, rapid, with normal dicrotism. The patient complained of constant aching in the upper dorsal region between the shoulder blades, in the region of the columns of Clarke. An attempt at a complete milk diet rendered the patient very weak and miserable and increased the tachycardia to such a point that the pulse could not be counted. The urine was examined by Bouchard's method once in February and again in March. On the first occasion the toxic coefficient was 5.79; on the second, .712. The patient had been treated with various nerve and vascular tonics without material benefit, before she came under the speaker's care, so that line of medication was abandoned altogether and attention was directed to disinfection of the intestinal canal. Various disinfectants were used at different times; for a long period, bismuth, salicyl, and beta-naphthol were given, associated with a daily flushing of the colon with two quarts of water. Under this treatment, and especially the colon flushing, the diarrhœa was arrested and the patient grew steadily stronger, and the menstruation returned on April 15, 1899, after an amenorrhœa of twenty-two months. The week before this happened a third examination of the urine gave a urotoxic coefficient of 1.426, nearly double the toxicity found in March. On April 21st the patient was feeling very weak, with much headache and anorexia, and the urotoxic coefficient was .388, the only time at which it was subnormal or other than excessive. On March 27th, after an experiment with thymus gland, the coefficient was 1.662. Menstruation occurred three days later, but after this it was absent until January, 1900, when it returned and has recurred regularly ever since. The last urinary examination was made May 22, 1900, and the coefficient was then nearly normal, being .432. The pulse remained at 120 or over with

scarcely an exception for eleven months; then, on January 24th, it became 100 and did not change in spite of an attack of diarrhœa and insomnia. On the 7th of February, 1900, the medication was changed to salicylate of sodium, of which from gr. lx. to gr. lxxx. were given a day. After ten days the pulse was found at 93, ten days later at 92, on April 4th at 90; the day before the report was made it was 93.

Dr. E. D. Fisher said that the case showed a very vascular condition of the thyroid gland. He did not absolutely agree with Dr. Jacobi in the use of intestinal antiseptics. He had had success with the use of strophanthin for long periods. That treatment might be carried out in a case of this kind.

Dr. William H. Porter said that he had seen recently two cases of a similar nature treated by antisepsis of the alimentary canal, and this had given better results than have been obtained under other treatment for that class of cases.

Dr. William H. Caswell said that glycerophosphate of sodium, gr. xv. three times a day, had been given in a case of this kind, and the improvement had been very marked. The pulse had fallen from 130 or 140 to 84 or 88, and had remained so for the last two months. All constitutional symptoms were very much improved, although the exophthalmos had not disappeared, nor was there any decrease in the size of the thyroid. The patient was, however, better and was still doing well.

Dr. Jacobi replied that this question of the urotoxic coefficient interested her, although she had paid no systematic attention to it. She had noted that when the urotoxic coefficient was in excess of normal, the patient was better. Once it fell below normal and she was decidedly weaker with symptoms of more constitutional poisoning, this confirming the idea that poison circulating in the blood and excess of urine toxicity coexisted with the effort of the organism to throw it out. When the toxicity was high, the patient was better; when subnormal the patient was worse.

Congenital Hydrocephalus of Non-Inflammatory Type.—Dr. Joseph Fraenkel presented this case. He said he thought it worth while to bring the patient, as the case seemed unusual in its clinical pathology, and he was in doubt as to the correct diagnosis. The child was twenty-six months old; it was born at full term without difficulty. The father was thirty-six years old, the mother thirty; they were Russian Hebrews. Both were perfectly free from taint of chronic disease. They had three other living children, all perfectly well. One miscarriage occurred prior to birth of this child. Immediately after birth the child was noticed to be abnormal. It did not hold its head up and gave no evidences of mind or brain development. The symptoms had since become accentuated. At no time had it walked, talked, or shown any signs of mental vigor. Obstinate constipation had existed since birth. All examinations had given a negative result. There were no evidences on the skeleton pointing to rachitis. The upper and lower extremities were rigid and permanently contracted, but the contracture could be overcome, and the reflexes were present. There was no ankylosis, and the reflexes were not exaggerated as would be expected. The child vomited at times and had had three or four general convulsions. After the last one reported, the child lost its voice for three or four days. Sensation in so far as it could be determined was normal. The head was somewhat large, 46 anthropometers in circumference, though not so large as in hydrocephalic infants usually. The fontanelles were not closed. The child was put on iodide of potassium and iodide of iron, and was thought to have improved, but objective examination showed no improvement. The speaker could make no diagnosis except that of hydrocephalus, but the history of the case was not in keeping with the general experience of that disease.

Dr. Fisher agreed with Dr. Fraenkel's diagnosis of hydrocephalus, non-inflammatory type, congenital. One case which he had seen showed a congenital condition of interference with the circulation through the fontanelles.

Dr. Fraenkel said he had made the diagnosis of hydrocephalus with some hesitation, and he was dissatisfied with it. In other cases he had seen, he had not noticed this constant rigidity and throwing back of the head. Taking into consideration the severity of the symptoms, the head was comparatively small.

Dr. Jacobi asked whether there might not be a correlation between the small head and the severity of the symptoms. For some reason the head had not yielded, causing greater intercranial pressure than in ordinary cases in which the skull was large and necessarily the pressure was less.

Dr. Lewis A. Connor said this question of increased intercranial pressure could be determined by puncturing and the use of the manometer measuring resistance. A manometer might be readily improvised by means of a bent glass tube with a short horizontal arm and a long perpendicular one, attached by a piece of rubber tubing to the cranium.

Dr. Peterson said that it seemed to him the fact of the fontanelles being open would show that there was not unusually great pressure. The case did not look like one of congenital hydrocephalus. In that disease there should be an unusual growth of the head. He had seen this rigidity resulting from basilar hemorrhage occurring during the birth of the infant.

Dr. Fraenkel replied that in this case the labor was distinctly noted to have been normal.

Multiple Neuritis Following Pneumonia.—Dr. Lewis Connor presented a case of this kind. He said he wanted to show the patient, not because the condition was unusual, but because of its unusual association with another disease. The man, forty-one years of age, came to the Hudson Street Hospital on November 7th with a lobar pneumonia of five days' standing, typical in history and physical signs. The consolidation involved the left upper and lower lobes and the disease ran a normal course up to the point of defervescence. Instead of clearing up at the end of the seventh or ninth day, although temperature fell, the consolidation remained, the case presenting the ordinary picture of delayed resolution, lasting two weeks beyond the allotted time. During that time the patient gave no evidence of any other trouble. Just at the end of this period of consolidation, three weeks from the beginning of the attack of pneumonia, it was noticed that his legs were weak and that there was some discomfort in moving them, and the left arm extensors were also paretic. In the course of a week the following picture was developed: Extensive, almost complete paresis of the extensors of the leg, tibialis group, and peroneal muscles, and extensors of the left arm, and slight loss of power in the right arm; no anæsthesia; some numbness of the tips of the fingers and an area of hyperæsthesia over the crests of the ilia on both sides; almost no pain except girdle sensation; very slight tenderness over the calves of the legs and the arms. The diaphragm was not moving properly, and in about a week from the beginning of symptoms of paralysis there was complete loss of function of the diaphragm with either forced or natural respiration. It was a severe multiple neuritis which ran a course of five weeks before any improvement could be noticed. The patient could now walk about and had recovered very largely the use of his left hand. It was six weeks from the time of disap-

pearance of function in the diaphragm before the first contraction could be recognized. So severe a neuritis was very unusual in lobar pneumonia; it was recognized as a possible complication, but an unusual one, and in those cases in which the speaker had found it the neuritis had been local or else of a mild type. As to frequency of involvement of the diaphragm in these cases of functional neuritis, he had not seen anything in the literature of the subject, but his impression was that it was not common. He had neglected to say that the man's history was good so far as syphilis or tuberculosis went. He had been accustomed to drink three or four glasses of beer or ale in the course of the day, and two or three times a week a glass of whiskey. The picture was not that of alcoholic neuritis, nor were the sensory symptoms less marked than they usually were in these cases.

Dr. Cunningham asked what the state of the pulse was during this attack, and whether there was any involvement of the vagus.

Dr. Connor replied that the pulse remained normal. Only the pupils were involved.

Dr. Cunningham said that in alcoholic neuritis the vagus invariably was affected several days before the diaphragm was involved.

Dr. Jacobi asked whether it was thought that there was any infection by continuity of inflammation from the leg to the diaphragm, affecting the motility of the phrenic.

Dr. Connor said that his idea was that it was purely a matter of toxism; delayed resolution, long maintained condition of consolidation with continued growth of the specific bacterium. This was a cause of toxism sufficient to produce this result, taken in conjunction with the damaged condition of the nerves from the man's alcoholic habit.

Dr. Peterson said that a case such as the one just reported was quite unusual; it certainly was one of simple multiple neuritis following pneumonia. The moderate alcoholism might not have been sufficient to produce neuritis, but the added toxic condition of the blood caused by the pneumonia was sufficient to bring it about.

Progressive Muscular Atrophy.—Dr. Caswell reported a case of this nature. A young woman, twenty-one years of age, came to the Vanderbilt clinic seeking treatment for weakness in the hands. She was a maker of artificial flowers. Five or six months ago her hands began to fail, and she could not work so easily as before. The speaker found upon investigation that from the time she was a young girl she had had difficulty in closing her eyes, and she did not smile and use her lips and mouth as other children did. She was not conscious of this, and had complained only for the past few months that her hands failed at work. He examined her and found a case which in almost every particular conformed to the type of primary progressive dystrophy described by Landouzy-Dejerine, beginning in the face with no hypertrophy, the atrophy showing later in the upper extremities. The lower extremities were fairly well developed for a thin girl. The arms from the elbows to the fingers were not atrophied. From the elbows to the shoulders there was marked atrophy on both sides. The pectoral muscles about the triangles of the neck were decidedly wasted and fallen away. When the arms were turned backward the superior angles of the scapulæ went into the triangles of the neck on both sides; when the hands were put forward, the scapulæ were winged. This was due to the atrophy and weakness of the lower portions of the trapezius and deltoid. The face was myopathic. The onset of this disease, Dr. Caswell said, was very insidious. Until the patient noticed something which interfered with the daily employment or manual labor, she did not seek treatment.

Dr. Peterson said that he had considered the Landouzy-Dejerine type very rare up to two years ago, rarer than the Erb juvenile form, but within the past two years he had seen four cases with perfectly typical syndromes. The history was usually indefinite except as to the eyes. The patients never remembered being able to close the eyes. This would lead the speaker to suggest that some cases occasionally met, of bilateral lagophthalmos, might turn out to be this disease. Several years ago he thought this form a variation of the Erb juvenile type. Now he thought it a different syndrome with a different pathological basis.

Progressive Muscular Atrophy.—Dr. Leopold Stieglitz reported a case of a man, thirty-three years of age, born in Germany, who came to this country four years ago; his father died of heart disease, his mother was living. He had one brother and four sisters, and said none of them had a trouble similar to his. He could not state exactly when his present trouble began. He had noticed for some years weakness in the legs and inability to lift them properly from the ground; in consequence of this he had difficulty in walking and tired easily. This condition became steadily worse. The speaker saw the patient four years ago at Mt. Sinai Dispensary. Upon examination he found very profound atrophy, no disturbance of sense, and slight signs of reaction of degeneration. The case was entered as one of the peroneal type of progressive muscular atrophy. Last February the patient returned to the dispensary complaining of weakness in the arms. Upon examination it was found that, besides the condition in the legs, there was a very pronounced typical condition of progressive muscular atrophy of the body. The atrophy involved also the gastrocnemius muscles of the calf and to a certain extent the muscles of the thighs. On both sides there were atrophy of the pectoral, hypertrophy of the deltoids, wasting away of the upper arms, typical drop-foot, and atrophy of the lower extremities. The diagnosis was the peroneal and juvenile types of progressive muscular atrophy or dystrophy. The electrical reactions, however, did not correspond to those one would expect in a case of this kind. They were normal in the upper extremities and absent entirely in the lower. The patient had winged scapulæ, protruding abdomen, and kyphosis—all indicative of progressive muscular dystrophy.

Dr. Fisher said that there was a fine-drawn distinction between the juvenile and peroneal types. From the conjunction of the two in the same patient, it would seem that they might belong to the same family.

Dr. Fraenkel said the three types of dystrophy were shown in this patient. The remarkable feature was the absence of any heredity. This condition was unusual, he said, so late in life.

Dr. Peterson agreed with Dr. Stieglitz that it was the juvenile type. He thought there was a marked distinction between the juvenile and the Charcot-Marie-Tooth forms. The two syndromes were not alike. One peculiarity in Dr. Stieglitz's case was that the legs below the knees were affected. He could not see why, in the Erb-juvenile form, other muscles were not involved besides the shoulder girdle.

Dr. Stieglitz said that the unusual feature was the commencement of the disease in the lower extremities. He had looked into the literature of the subject and could find nothing that exactly corresponded with this case. The involvement of the lower legs was not so unusual, and in this case simply the muscles below the thigh sequence were involved. Atrophy of the muscles of the thigh was common in progressive muscular dystrophy. He thought a distinction should be made between the Charcot-Marie-Tooth and the Landouzy-Dejerine types on account of the difference in pathol-

ogy. The former was a disease of the cord; the Landouzy-Dejerine type was a pure myotrophia. On that account we should not try to connect the two syndromes. Unless the family history was carefully investigated we might be misled, for the disease might be hereditary without its being found out from the statements of the patient.

Hereditary Cerebellar Ataxia.—Dr. M. Mailhouse presented a case of this affection so-called. The patient, F. F——, was admitted to the New Haven Hospital January 13, 1900, with the following history: Age, thirty-two years; single; birthplace United States; occupation, postal clerk; the father and mother were living and well; he had five sisters living, all in good health. One sister died of pulmonary tuberculosis and another died in infancy of some cause not stated. The mother's mother also died of pulmonary tuberculosis. A sister of his mother was at present an inmate of the Connecticut Asylum for the Insane. Both mother and father have had muscular rheumatism. The patient had scarlet fever and diphtheria at fifteen years of age. When a boy he had rheumatism of mild degree. In 1887 he had a sunstroke which left him confined to his bed. He never had syphilis, alcoholism, or tuberculosis. According to the history taken on his admission to the hospital, the patient first noticed in 1887 a dragging of his toes on walking and that his shoes curled up, and were worn at the toes; he did not walk with a stamping gait and could direct his feet anywhere without trouble. The legs did not cross in walking. On closing his eyes while standing he was unable to keep his balance. He had no pain in the legs, but considerable backache. Then his hands began to tremble (1888), and his legs shook on walking. These symptoms increased and he had to use two canes in walking in 1888, in 1889 he used a crutch and one cane, and in 1890 two crutches. He had lost fifty-seven pounds in weight within the past ten years. He had headaches, off and on, not severe. He also stated that when twenty-one years of age he noticed an inability to run; he could walk, but when he ran his legs got mixed up as though they were playing cross-tag with one another. For the past four or five years erections had been incomplete, and at one time he had frequent urination. In his present state he appeared to be a man above medium height, of good frame but somewhat emaciated. A striking feature as he stood supported by his two crutches was the nodding tremor of his head; this was aggravated by walking. There was marked asymmetry of the head, a flattening of the occiput, and pronounced sloping of the forehead, with considerable flattening over the left parietal region. There was some facial asymmetry also, as was evidenced by a greater prominence of the right supraorbital arch than of the left. The nose was directed toward the right, and the left palpebral fissure was smaller than the right. His gait was markedly ataxic; he was able to get about fairly well on a level with the aid of crutches, but lost his balance readily on attempting to ascend steps. There was absolutely no muscular weakness in his legs. The knee jerks were present, but not exaggerated. There was no ankle clonus. The Romberg symptom was present, and the patient was supported with difficulty when he stood with closed eyes. There was no impairment of sensation of any one of the forms, from head to toe. His movements were quickly performed, jerky, as was observed when he attempted to touch the tip of his nose with the index finger, the eyes being closed. The ataxia of the upper extremities was much less evident than that in the legs. His speech was noticeably affected, but changed, being sometimes scanning or staccato and at other times characterized by indecision and unsteadiness in the muscles of vocal expression; it was decidedly an ataxic speech. The pupils reacted neither to light nor to accommodation. There was marked lateral nystagmus, and when the patient looked upward a rotatory nystagmus occurred; when the eyes were at rest there was no oscillation. There were no contractures and no scoliosis. The grasp of the hands was strong and the muscles of the arms showed no loss of power. The pectoral muscles were wasted, otherwise no atrophies were present. There were no optic atrophy and no limitation of the visual fields, but the man was myopic, requiring a lens of seven diopters. The superficial reflexes were present, the plantar being very active. The urine presented no abnormality. The handwriting was like that of a tabetic. A review of the symptoms, Dr. Mailhouse said, revealed the marked ataxia of the whole muscular sytsem without any paralytic phenomena. The case resembled one of Friedreich's ataxia in its mode of development and general appearance, but differed from the typical disease in its later onset, in the retained knee-jerks, in the late and mild affection of the arms, in the loss of the ocular reflexes, and in the absence of contractures or paralysis; the man had been afflicted twelve years and there was no paralysis or contracture present. The question might arise as to the disease being multiple sclerosis, but the speaker believed that this affection could be ruled out by the mode of onset, it being ataxic rather than paraplegic, by the normal reflexes and sensory phenomena, and by the absence of intention tremor. Furthermore the long duration of the illness without any paralysis, ocular or corporal, would militate against such a diagnosis. The case was presented not as an argument in favor of the type of hereditary cerebellar ataxia, but rather as a clinical example of ataxia presenting such a symptom complex.

Dr. Caswell said that in the form of ataxia described the fundus was generally affected; there was more or less neuritis and the knee jerks were increased, and in this way discrimination was made between cerebellar and ordinary ataxia.

Dr. Fisher thought the sunstroke might have been an etiological factor in this case. He said he remembered a case of sunstroke followed by symptoms of this type, resembling compound or multiple sclerosis, not conforming strictly to either. Taking that as an etiological factor, there were ordinarily some meningitis, some change affecting the cortex of the brain leading to the ataxic symptoms; accordingly ataxia was seen with inco-ordination of the muscles, a spastic condition—a degenerative condition secondary to some such lesion as that caused by the action of the sun.

Dr. Fraenkel said there was a great difference between cerebellar ataxia and ataxia produced by disease of any other parts of the co-ordinatory system.

Dr. Peterson said he had examined the man before the meeting and thought the diagnosis lay between multiple sclerosis and cerebellar ataxia. He was inclined to think Dr. Mailhouse was right in his diagnosis of cerebellar hereditary ataxia, on account of the pupillary condition—no reaction to light—and because the man had more of an ataxia than tremor of the ordinary multiple-sclerosis type.

Dr. William B. Pritchard asked whether there was anything of note in the subjective history of the case as regards vision, hearing, or persistence of vertigo or headaches, that added to the data.

Dr. Mailhouse said there were no subjective symptoms at all, except backache and difficulty of manipulating the legs. The man was strongly myopic, but there was no eye-strain.

Raynaud's Disease of a Gangrenous Type.—Dr. William H. Porter presented a case of this kind. The man came to this country some years ago; for a year or so he was a hod carrier, then went into an iron foundry, where he had worked since. He had a very

pronounced alcoholic habit, and used tobacco to a considerable extent. In the middle of April he noticed that the fingers of both hands were very white and icy cold. This lasted for two weeks and was followed by superficial gangrene, discoloration and blackness of the four fingers of both hands, a little discoloration of the left ear, and a spot on the opposite ear. This condition lasted for ten days before he came to the hospital. He suffered intolerable pain and got very little sleep. The urine showed slight traces of albumin, a decrease in urea, and a large amount of indican. The patient had a very high pulse and was given doses of nitroglycerin with strychnine and caffeine to improve the circulation. Lead and opium dressing was applied and gave relief.

Dr. Pritchard said that the patient had been under his care for three or four weeks. At that time the man had, in addition to the symptoms mentioned, extreme œdema of the hand, extending beyond the wrist. He had almost the national combination of colors—blue finger tips, red hand, white arm. He was not relieved by the lead and opium applications made in varying strength, and by other local means. He admitted a rather gross alcoholic history, and those who saw him at the time were of the opinion that that was an etiological factor of some importance, possibly intensified by the extremes of heat and cold to which he had been exposed. His sufferings were horrible. Opiates were given in moderate quantities, only to modify the extremity of pain

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 15, 1900:

	Cases.	Deaths.
Tuberculosis	223	128
Typhoid fever	116	28
Scarlet fever	45	3
Measles	26	5
Diphtheria	111	20
Laryngeal diphtheria (croup)	3	1
Cerebro-spinal meningitis	0	6

Bronchitis in Children.—Oppenheim says that in the treatment of bronchitis in children the parents must by all means free themselves from certain time-honored beliefs which should be called superstitions. Children suffering from this disease need not be swathed in blankets and pads until they resemble mummies; they need not be kept unwashed during the course of the sickness, and they will not be killed by a breath of fresh air. On the contrary, they should be kept comfortably warm but not hot; they may with advantage have a warm bath morning and night; and the sick-room should always be kept well ventilated. One should keep in mind that most of these cases are examples of germ infection, and that they require a vigorous excretion, a satisfactory stimulation, and a bland soothing of the cough and pain.

Hints to Contributors to the Medical Press.—Professor Virchow, the editor of the *Archiv für pathologische Anatomie*, has addressed some words of counsel to the contributors to that periodical and to medical authors generally, explaining several points which it is desirable that writers for the medical press should always keep in mind. It would be difficult to find a higher authority on this subject than Professor Virchow, the patriarch of the savants and editors of Germany. His remarks are not intended for authors of books, who are at liberty to write as they like; they have been published exclusively for the benefit of contributors to medical weekly, monthly, or quarterly journals. He says that it is one of the elementary principles of journalism that the successive numbers of a journal must be issued at a certain time and in a certain size. Contributors must therefore endeavor to write concisely, taking up as little space as possible and avoiding all superfluous matter. Descriptions of cases, experiments, and necropsies when sent to editors for publication are often so voluminous that it is impossible to use them without serious inconvenience. The publication of series of cases, etc., in the form of tables is a great annoyance for the editor, the printer, and the readers. Controversies as to priority are often offensive in style and lacking in the courtesy due to professional brethren. Finally, contributors ought to abandon the custom of quoting long passages from other authors with the object only of showing their knowledge of medical literature.—*The Lancet.*

The Earliest Signs of Tuberculosis.—Professor Bozzalo, of Turin, in a paper read at the recent International Congress on Tuberculosis at Naples, has conveniently summarized the following eleven important points which are of assistance in forming a diagnosis of pulmonary phthisis in its earliest stages. They are as follows: (1) Albuminuria alternating with phosphaturia; (2) a pseudo-chlorosis distinguishable from true chlorosis by the slighter degree of reduction of the hæmoglobin and by the less marked vascular and cardiac disturbances (palpitation, soft pulse, pulsating arteries, etc.); (3) the presence of gastric disturbances like gastralgia, anorexia, nausea, and vomiting; (4) tachycardia in the absence of fever; (5) diminution of blood-pressure; (6) a rise of temperature following bodily or mental exertion above the slight rise proper to health; in women a rise of from 0.3° to 0.4 C. is observable before the onset of each menstrual period; (7) an undue tendency to sweat after exertion, mental or bodily, also night sweats; (8) pain in the supra-orbital regions and in the neck; (9) a slight inequality of the pupils with a tendency to dilatation (mydriasis); (10) the occurrence of herpes zoster; (11) enlargement of the spleen. Of these the first seven symptoms are the most frequently met with and possess considerable diagnostic value.—*The Lancet.*

The Hospital Ship "Maine."—Following is an account of the work of the American hospital ship *Maine*, now in Chinese waters, written by Mrs. Kinnicutt, one of the hospital officials of the State of New York, and published in *The Tribune*:

"The American hospital ship *Maine* arrived in Chinese waters on Saturday, August 25th. So little is known in the United States of her mission, either present or past, that I ask leave to acquaint your readers with what she has accomplished and what she still aims to do for the relief of suffering humanity and for the credit of our country in distant parts of the world. The idea of a hospital ship originated with an American woman, the wife of an American long resident in South Africa. This ship, generously loaned by the Atlantic Transport Company, through its president, Bernard Baker, of Baltimore, equipped and maintained at the cost of Americans, and in charge of American doctors, started on an errand of mercy in December last for Cape Town, to give aid to the sick and wounded in the South African war. As a volunteer ship, supplementary to the government relief ships, she was fitted out with many comforts and luxuries such as cannot be demanded in times of stress from an overtaxed War Office. In the harbors of Cape Town and Durban the *Maine* received both the British and the Boer wounded, and returned in April to South-

ampton, Eng., with a full complement of invalided British soldiers. The number of patients received on board was three hundred and fifty-four, including those treated in port. Re-equipped and re-victualled in nine days, she sailed directly back to South Africa to bring home another shipload of disabled soldiers. On this her second return voyage, in July, I was one of those who sailed out from Southampton to welcome her. For me it was the first and nearest approach to the horrors of war, and I found them, even in this their second stage, sad and grim. As our boat approached the incoming *Maine*—this moving hospital, larger in its number of beds than most of the large hospitals of New York—we saw her sides and decks crowded with eager faces; men everywhere in invalid chairs, on stretchers and on crutches; with legs gone, arms gone, heads bandaged, and all in motley array. No gay trappings of dress parade, only here and there a cap, a Glengarry or a fatigue jacket, to indicate the soldier's uniform. We boarded the *Maine*, and during the two hours before we reached the dock at Southampton there was ample opportunity to examine her. Descending into the first ward—named after Mrs. Whitelaw Reid—we found a number of patients in the cots. It was unnecessary to ask the nature of their trouble, for the pale faces and emaciated bodies bore the unmistakable stamp of enteric fever—that deadliest of camp followers. The ward was bright and well ventilated, the bed-linen fresh and white, and everything scrupulously clean. Over each bed was suspended the name of its American donor—men and women with sympathies broad enough to stretch forth into the unknown for the unknown. The ward capacity of the *Maine* is two hundred and ten beds. The surgeons and physicians, all of them first-rank men from our best American hospitals; the nurses from the Mills Training-School, and the orderlies, were a strong, sturdy band, truly a staff upon which to lean. Despite the comparatively cramped quarters, modern scientific treatment had been carried out in the form of tub baths for the cases of enteric fever with gratifying results. By means of an admirable Roentgen-ray apparatus sent out from New York valuable assistance had been obtained in the treatment of gunshot injuries, and in a well-equipped laboratory diagnoses in doubtful cases had been made by bacteriological examinations. A strange and a happy fact to be recorded was that during the three weeks' voyage of this hospital ship not a single death had occurred. The patients below deck, as well as above, were in excellent spirits, despite their disabilities, and one and all seemed grateful for what they termed their good luck in having been consigned to the 'Yankee ship.' At Madeira a few newspapers had been obtained telling of the outbreak of trouble in China, and all were eager for the latest war news. 'Soon we'll be fighting together out there,' a bright-faced Irishman said to me, with evident impatience to be himself in the fray. When I expressed my preference for soldiers as guardians of peace rather than as forces for war, he looked quite disgusted, and said: 'But, ma'am, what would we be afther doin' without a bit of a stir-up oncet in a while?'—truly a characteristic race point of view of the interest and pleasures of life. As we approached Southampton the *Maine* received a hearty welcome from the American training-ship *Lancaster*, whose yards were manned with lusty lads. Across the end of the Southampton dock a large sign was stretched, 'Telegrams sent free,' and soon every soldier on deck was scribbling a home message. It had been the intention of the London executive committee of the *Maine*—all of whom are women of American birth, whose energy, efficiency, and devotion are deserving of home recognition—again to send her back to South Africa. But the crisis in China had become so acute, the provision for many sick and wounded of the allied forces so urgent, with no hospital ship as yet under way, that the committee decided that the need for their ship was now greater in the far East than in the far South. A proposal to this effect met with cordial approval at the British War Office, and on July 12th the *Maine* set sail for Chinese waters. She was reported on August 25th as having arrived at Hong Kong, on her way to her northern station to receive the wounded. Directly after the departure of the *Maine* the committee notified the United States government at Washington of her intended destination, and offered a welcome and all possible aid to our sick and wounded countrymen. The American ambassadors at the courts of the allied Powers were also informed of the departure of the *Maine* for China, and asked to notify the governments to which they were accredited that their wounded would receive a cordial welcome on the American ship. Prompt and appreciative acknowledgment has been received from Germany, Italy, Austria-Hungary, and the other powers. A check for £1,000—a most timely and welcome gift—was also received from Mrs. Corning Clark soon after the departure of the *Maine*. Mrs. Clark asked that the sum be used, if possible, to aid the men of the Ninth United States Infantry—the first American regiment to suffer in the field. J. P. Morgan & Co., No. 23 Wall Street, are the treasurers of the *Maine* fund in New York.

"This is the history, so far, of the American hospital ship *Maine*. If with this name is to be linked the word 'remember,' may it be, in the future, with this sister ship of mercy, whose activities and sympathies, true to her Red Cross flag, are world-wide and world-embracing."

The Plague Bacillus.—Dr. H. Noguchi has been conducting some experiments at Newchwang, China, with the plague bacillus, to determine its resistant power against cold in dry conditions and in frozen liquid media. His results, which are tabulated in the report of the United States Marine-Hospital service for July 13th, are as follows: "That the plague bacilli are not devitalized by the temperature of 24° C. below zero even after being submitted to this temperature for the space of three weeks. The peculiarity possessed by the plague bacillus is the limit of temperature for its multiplication, not like other pathogenic germs. It can grow uniformly, slowly but steadily, from 20° to 37° C. which is rarely observed in other bacteria. . . . The plague bacilli if laid near the freezing-point stop their growth and remain for a long time inert waiting for further chances of good hosts. . . . From the several reports published by the German plague commission to Bombay, I have learned that the pneumonic forms are comparatively few, while the official report of the sanitary board of Germany showed that the majority of cases in Odessa were of pneumonic form. Of course the nature of an epidemic is influenced by the climate and the resistance of the plague bacilli on one side, and it also depends greatly upon the customs of the nation. . . . In India, where the hot air and dry soil are very unfavorable to the floating bacteria to retain their lives even for a few minutes, the pneumonic forms are produced by the direct contagion with fingers, or pipes, etc., of the patient, or particles of sputum. . . . In contrast to India, Chinese houses are furnished with favorable conditions for the plague bacillus—bad ventilation, little direct sunlight, a heaping of human excrements, etc., especially the earthen floor must be regarded as a most dangerous source of infection. . . . Chinese people do not use spittoons in their rooms, and spit anywhere; indeed I have seen that the pneumonic patients were spitting their bloody sputum on the beds,

windows, walls, or floor at the agonal stages, and the relatives trampled the sputum into powder within a few minutes."

Demand for Antitoxin.—At the recent meeting of the British Royal Institution of Public Health at Aberdeen, Dr. Dean, who has charge of the farm where the antitoxin is manufactured for the Jenner Institute, referred to the seasonal fluctuation in the demand for antitoxin. He used the facts of his experience at the Jenner Institute to show that the supply of antitoxin varied according to the seasons much in the same way as the deaths from diphtheria. The curve shown on a chart was formed on the basis of the number of doses sent out each month of the year. This was correlated with the corresponding one of diphtheria deaths in the registrar-general's returns, and although they did not show an exact correspondence, the variation was sufficiently slight to justify the conclusion that the supply of antitoxin was a real indication of the seasonal variations in the prevalence of diphtheria. Taking the average of the last twenty years they were lowest in the month of May and highest in the month of November, while in precisely the same months the supply of antitoxin was highest and lowest respectively.

Mortality in War.—In the London *Times* of September 1st, an interesting comparison is drawn between the rates of mortality which prevailed among officers and men during the Franco-German war, and those incurred by the British army in South Africa. The mean strength of the British army, including all forces, may be taken to have been 5,266 officers and 188,000 non-commissioned officers and men. The deaths have been: officers killed or died of wounds 380, died of disease 160, total 540; non-commissioned officers and men killed or died of wounds 3,580, died of disease 5,980, total 9,560. The rates of mortality were as follows: of the officers 72.1 per 1,000 were killed or died of wounds, and 30.6 per 1,000 died from disease; total 102.7 per 1,000. Of the non-commissioned officers and men 19 per 1,000 perished in battle or died of wounds, and 31.8 per 1,000 died of disease; total 50.8 per 1,000. In the Franco-German war official figures show the fortunes of a mean strength of 25,960 officers and 862,800 men who took part in that campaign. Battle and wounds accounted for 1,650 officers and 26,627 men, while 144 officers and 10,942 men met their deaths from disease. The rates of mortality were: officers 65.5 per 1,000 killed or died of wounds; and 8.9 per 1,000 died from disease and other causes; total 74.4 per 1,000. Non-commissioned officers and men killed or died of wounds, 30.9 per 1,000, died from disease, etc., 14.2 per 1,000; total 45.1 per 1,000. As with British forces in South Africa we see a large discrepancy between the number of officers and of men killed in battle, but while in the Franco-German war an officer had a double chance of being killed as compared with his men, in South Africa the British officer had to face three and a half chances. As regards the men, the risks in the Franco-German war, as compared with those in the South African compaign, were 50 per cent. greater of being killed in battle, and less than half as great of dying of disease. When every allowance is made for the conditions under which the Franco-German war was carried on, the highly civilized and thickly populated country, and the ease with which medical comforts and assistance could be commanded, it is remarkable how low the death rate was from disease. In South Africa officers and men have died of disease at the rate of 31.7 per 1,000, while the rate for officers and men in the Franco-German war was only 12.5 per 1,000, that of officers alone being as low as 8.9 per 1,000. Indeed the Franco-German disease rate was some points less than the ordinary rate of 15 per 1,000, experienced by British troops on foreign service in time of peace.

German Military Expedition to China.—The care of the troops embarked for China has been an object of great solicitude to the military authorities, and all the officers have received a small pamphlet containing hygienic rules to be observed on board ship and in the far East. The pamphlet is written in a style intelligible to the ordinary reader, and the officers have been ordered to give their men instruction in the subjects dealt with in it. This is the more necessary as the China expedition is the first in which German troops have been engaged on a large scale out of Europe. The troops have been provided with different uniforms for the hot and cold seasons; the summer uniform consisting of khaki and a straw hat, the winter uniform of stout cloth and furs. With a view to prevent scurvy and similar disease great quantities of preserved vegetables and anti-scorbutics have been sent to China. Apparatus for the sterilization of drinking-water by boiling and by bromine, as suggested by Dr. Schumberg, has also been provided. Army medical officers specially trained in bacteriological work have been sent with the army, and it will be their duty not only to examine the food and the drinking-water, but also to investigate any conditions which might have a significance in connection with an outbreak of disease. The army medical corps is, of course, much more numerous than in a European war; army medical officers being sent for each 129 men. The special medical staff consists of a bearer company and of four field hospitals for 200 patients each. For the erection of stationary hospitals one hundred and twenty-seven tents and fifteen barracks have been sent with all the necessary staff and material. Two hospital ships have been chartered from the North German Lloyd for the conveyance of sick and wounded soldiers to Europe.—*The Lancet.*

Strong Solution of Tar in Eczema.—Jonathan Hutchinson's favorite prescription for almost all forms of eczema is a combination of liquor carbonis detergens and liquor plumbi subacetatis. A teaspoonful of each to a pint of warm water is a common prescription which should be used not only as a wash, but kept constantly applied on lint. But in some cases a more convenient method is to apply a very much stronger preparation for only a few minutes at a time. The undiluted liquor carbonis alone is often effectual for the relief of pruriginous affections. It stings at the moment of application, but it relieves the itching and does not cause smarting afterward. A surgeon for whom the writer prescribed found that equal parts of the liquor plumbi and liquor carbonis applied undiluted always killed eczematous patches. —*Archives of Surgery*, vol. xiv., p. 345.

Adulteration of Coffee and Tea on the European Continent.—James Du Bois says that, if all the substances that pass through a continental coffee-grinding machine during the year should be written in alphabetical order, A would begin the list with acorns, and W would end it with wormwood, sprouts of which are sometimes used to give the debased coffee a slight aromatic bitter taste. Adulteration occurs largely in the coffee that is sold in the ground form. Several coffee-berry factories have been discovered in Europe which are doing a large and profitable business by moulding an admixture of tan bark, stove rust, clay, sawdust, chicory, coffee sediment, and coffee meal into a neat berry by the aid of some agglutinant, and these

berries were so well made that the deception was not discovered for a long time. This production had a large sale among the lower classes of Russia and Poland, and mixed with the genuine coffee berry its sale was quite lively in other parts of Europe. Unroasted coffee berries are often made from oat and rye flour and corn meal. The natural aroma of these grains is destroyed by some process, and after the proper amount of coffee aroma is added the berries are formed and caused to maintain their shape by some adhesive substance. The test usually employed to discover this deception is to place the beans in a receptacle containing water; this will dissolve them in a few hours. The debasement of tea is a growing industry. Twenty-five years ago the tea-drinking habit was confined to Holland, Russia, and England, but the beverage is now popular in almost every continental country. This new condition increases the demand, and the adulterators thus have the opportunity to ply their nefarious trade with success. Take a handful of ordinary tea and place it in lukewarm water, and when the leaves are thoroughly saturated open and spread them out, and three chances in six you will find a quantity of strawberry, linden, sage, and other leaves in the collection. But should it be found that all of the leaves belong to the tea plant that will be no proof that adulteration has not taken place, for the clever Chinese have a trick of using the old leaves of brewed tea for the export trade, and some of the tea dealers of Europe have discovered the deception and are utilizing the trick by preparing these leaves themselves.—*The Sanitarian.*

Production of Ipecacuanha.—One of the most widely used of all vegetable drugs is the powerful emetic ipecacuanha, which is obtained from a Brazilian shrub. The French conseiller de commerce at Cuyaba, state of Matto Grosso, gives in a recent report an interesting account of this plant, which has in that state and the neighboring district its only habitat. The drug is obtained from plants which attain a height of from twelve to sixteen inches. The leaves are oval, dark green, and sharply ribbed, and the white flowers give place to an ovoid fruit containing black seeds. Besides the ipecacuanha cephœlis or the "white ipecacuanha," as it is generally known, there are several other varieties which are somewhat different, but all are used for the same purpose, and are distinguished as brown, black, and striated ipecacuanha. The drug is obtained from the root of the plant, where it occurs in quantities about the size of a quill between the layers. The state of Matto Grosso, which, as before observed, is the habitat of the plant, is one of the richest in Brazil, among its many natural products being gold and diamonds, rubber, sarsaparilla, jalap, jaborandi, and copaiba. Ipecacuanha is found in the north and northwest of the San Luiz de Caceres, formerly in the Villa Maria region, and its habitat covers an immense area between a network of rivers in Brazil, Bolivia, and Paraguay. The dense foliage of the forests of this region provides the dank and humid conditions which favor the growth of the shrub. The Brazilian product is known as Rio ipecacuanha, and the product procured from similar shrubs in other countries passes under the name of the port whence it is shipped. Attempts have been made to transplant the shrub and to cultivate it in British colonies in various parts of the world, but without success, and Brazil continues to be the only source of supply for the best grade.—*Scientific American Supplement.*

Yerba Maté Tea.—Some of the British consuls in South America, says the London *Times*, refer in their last reports to the virtues ascribed to the tea made from yerba maté, a herb which takes the place to some extent of tea and coffee, and which is derived from the leaves of the Ilex Paraguaensis, a tree of from twelve to twenty feet in height. The consul in Paraguay says this tea is consumed by a large proportion of the populations of Brazil, the Argentine, Uruguay, Chili, and Paraguay. The leaves are gathered every two or three years and dried over a slow fire; they are then pounded in mortars on the ground, and finally packed in fresh skins and dried in the sun. The tea is made by pouring boiling water on the leaves, which serve for several infusions. The taste is bitter but not unpleasant, and the effects are asserted to be invigorating. It is said that it would be valuable as a restorative to troops on the march, and the French government has ordered a shipment of maté for the colored troops. Some samples have also been sent to Germany for experimental purposes. An attempt is also being made to introduce it into the United States as a suitable beverage for the working classes. When analyzed the tea is shown to contain caffeine and caffeotanic acid in important proportions. The consul-general at Rio also refers to the subject as one of commercial interest. It is claimed on behalf of the tea that it possesses superior stomachic properties to tea and coffee, in that while it is refreshing and invigorating, and favorable alike to mental and physical exertion, it does not disturb the nervous system. But even Brazilians are not agreed as to its merits, some alleging that by its aid the most arduous work can be done, such as forced marches on short rations; others asserting that in war coffee has proved much more sustaining. However this may be, it is largely consumed in South American countries, where the price of low-grade China teas is too high to admit of their shipment to South America, and it is therefore possible that it has some good qualities to recommend it.—*Science.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 15, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Alaska, Nome	August 18th	3	
Colorado, Jefferson Co.	August 28th to September 1st	11	
Las Animas Co.	August 28th to September 1st	1	
Kansas, Wichita	September 1st to 8th	1	
Louisiana, New Orleans	September 1st to 8th	2	
Minnesota, Minneapolis	September 1st to 8th	1	
Winona	August 28th to September 4th	3	
Ohio, Cleveland	September 1st to 8th	2	
Dayton	September 1st to 8th	1	
Texas, Eagle Pass (in Mexican portion of town)	September 7th	1	
Utah, Ogden	August 1st to 31st	2	
Salt Lake City	September 1st to 8th	1	
West Virginia, Wheeling	September 1st to 8th	1	
Smallpox—Foreign.			
Austria, Prague	August 18th to 25th	2	
Belgium, Antwerp	August 18th to 25th	1

SOME PERSONAL OBSERVATIONS ON THE EFFECTS OF INTRAPLEURAL INJECTIONS OF NITROGEN GAS IN TUBERCULOSIS.[1]

BY HENRY P. LOOMIS, M.D.,
NEW YORK.

IN such a disease as tuberculosis we herald with avidity anything which seems to abate one jot of its virulence, or which seems to assist, in any way, the processes of nature toward restoration to health.

In looking back over professional work it is undoubtedly the experience of many that certain cases stand out in the memory with prominence and distinctness, especially those that have an unusual culmination. Such a case, occurring several years ago in my practice, made a deep impression upon me. It was that of a man with advanced tuberculosis of one lung, who, losing flesh rapidly, had apparently but a few months to live. The patient was confined to his room with all the constitutional symptoms of advanced tuberculosis. Suddenly the pleural cavity on the affected side became filled with serous effusion. I was surprised to notice at once a marked change in the patient's condition. All the constitutional symptoms improved and he began to gain in flesh, and at the end of two months was able to return and take charge of an active business. He remained apparently well, until, at the end of four months, as the fluid seemed so thoroughly to fill his pleural cavity, I decided to withdraw it. After tapping he became worse at once, and finally died. The inference is that, had I left the fluid alone, the man would have continued in his improved condition, and I have no doubt that many observers can recall cases in which ordinary apical tuberculosis suddenly starts to improve, and the patient, from being in a desperate condition, becomes comparatively well, this change following a filling of the chest cavity of the affected side with the effusion, the result of tuberculous pleurisy.

It has been estimated that three-fourths of the cases of primary pleurisy are tuberculous, these statistics being based upon the future histories of cases of pleurisy with effusion; and it has been found that months or years afterward pulmonary tuberculosis develops on the side where the pleurisy had been. May not the explanation at least of some of these pleurisies be that they have developed secondarily to a slight pulmonary lesion of the lung, which is quickly rendered quiescent and possibly cured by the pressure of the effusion, and later this pulmonary lesion lights up, not as secondary to the pleurisy but really as the primary condition preceding the effusion? Clinical experience has proved that the results upon pulmonary tuberculosis when empyema develops upon the affected side are much more favorable than when there is a serous effusion. In one hundred and sixty-four cases of empyema operated upon by Koenig, Cabot, and Runeberg, one hundred and forty-four resulted in recovery. This shows what a favorable termination empyema may have. Considering that it is proven to be secondary to tuberculosis in eighty-three per cent. of all cases, it certainly speaks favorably for its curative effect upon the lungs. The explanation of this fact is no doubt that in an empyema the compression of the lung is maintained for a much longer time and is even more or less permanent, on account of thickening and the adhesion which prevents the expansion of the lung. The curative effect upon tuberculosis by this compression impresses upon us the fact that tapping and drainage should be resorted to only after careful consideration, and only when special indications arise, for statistics collected by Czernicki and Boumber have proven conclusively that quiescent tuberculosis of a lung compressed by empyema may be aroused to activity by such expansion as follows every thoracotomy or aspiration.

Again, it is a well-known clinical fact that pneumothorax developing in the course of pulmonary tuberculosis produces salutary changes in the tuberculous process which not only arrest the course of the disease, but ameliorate the general symptoms and sometimes produce a cure. Osler and Pepper both call attention to this fact, and I think all of us have been surprised at times at the unexpected improvement in cases of phthisis following upon the development of a perforation and the filling of the pleural cavity with air. Dr. W. F. Hamilton, of Montreal, reports six cases of pneumothorax occurring during the course of pulmonary tuberculosis. All these patients were failing gradually before the perforation. After it occurred two died in a short time, one lived for seven months, and the other three recovered.

In those cases of pulmonary tuberculosis reported as ending in complete recovery, the perforation becomes healed and the effusion is absorbed as well as the contained air or gas, and the lung again performs its function, depending, however, somewhat upon the degree of infiltration of the tissues present. Whatever may be the explanation of the phenomenon, the clinical fact remains that compression of the lungs—as occurs in the three classes of cases which I have just mentioned—has a beneficial effect on pulmonary tuberculosis. As is well known, the most brilliant successes in the treatment of tuberculosis have been in the cure of tuberculosis of the joints. The treatment which gives this result is simply immobilization and the enforced physiological rest to the joint. May this not be the explanation of the fact that in those cases of pleurisy with effusion, empyema, or pyopneumothorax, the compression of the lung brings about a condition somewhat similar to that which is obtained by the surgical treatment of the joints?

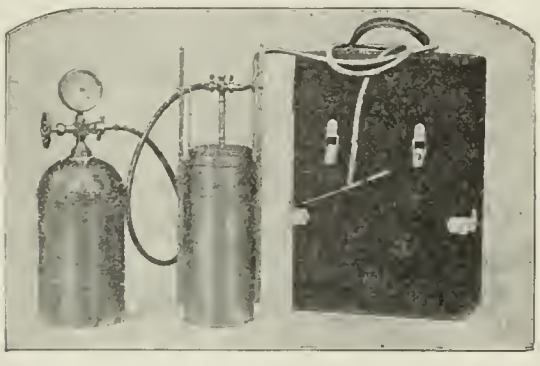
The enforced rest of the lung as a respiratory apparatus aids in the encapsulation and favors the cicatrization of the tuberculous foci. It does more: it enforces drainage of secondary deposits through the bronchi, aids the healing of cavities by approximation of their walls so that the condition is brought about which is sought for every day by the surgeon in the healing of abscesses—the emptying of the cavity and the drawing together of its walls. Possibly the most important element in favoring the elimination and

[1] Read before the American Climatological Association, Washington, D. C., May 2, 1900.

final cure of the tuberculous areas in those lungs rendered quiescent by compression is a gradually diminished lymphatic circulation. This lessens at once the danger of the most common complication of phthisis, namely, the dissemination of the tuberculous products along the lymphatic vessels.

The quiescent condition of the lungs also stops almost completely the transmission of infection into uninfected bronchi, and yet all the time the circulation is not interfered with to any extent, and fibrosis is favored—an ideal condition for the healing of pulmonary tissue, it seems to me. Dr. Lemke, of Chicago, cites an interesting case in this connection. It was a case of miliary tuberculosis involving the whole lung with the exception of one lobe, which escaped the infection entirely, and this lobe was compressed by a pleuritic inflammation.

Nature, when she heals tuberculosis by this principle of immobilization and enforced rest, as is seen in cases of empyema, causes a contraction of the chest wall in proportion to the amount of tissue involved. Moreover, successful operations for empyema are dependent on thorough resection of the ribs so as to favor complete collapse of the lung and obliteration of the empyemic cavities. Post-mortem examinations which have been made when the lung from any cause



has been compressed for a long time show that a certain degree of fibrosis has developed. Rokitansky has proven this by a number of pathological investigations.

If clinical experience proves, as it seems to me to do, that compression of the lung favors the healing of a tuberculous process, what means have we to bring about this artificially? It has been proposed to apply a plaster jacket to the whole of the affected side so as to obtain immobilization of the thorax. Migelion, in *La Médecine Moderne*, reports thirty cases of phthisis which he treated in this way. He states that the jacket was worn in all cases excepting two, without discomfort. He reports favorable results. Again, upon the same principle, others, such as Dr. Stewart Tiday and Dr. Dennison, recommend strapping the chest. It hardly seems to be probable that much compression can be brought about by this means. Others have proposed resecting a portion of bone over a cavity or extensive pulmonary lesion, and so causing a falling in of the chest at that point, producing a localized compression. Turban[1] reports the case of a young man twenty-one years of age with extensive involvement of the left lung, this being almost entirely destroyed. He did an extensive resection of the fourth, fifth, sixth, and seventh ribs without entering the pleural cavity. The chest contracted gradually. He did a second operation and removed more of the sixth and seventh ribs and also portions of the eighth and ninth ribs. The symptoms ameliorated and the patient recovered (?).

All these methods seem to me to be crude and ineffectual. After my experience with the case referred to at the beginning of this article, which showed such improvement on the development of pleurisy, I carried on a series of experiments for a number of months, endeavoring to fill the chest cavity with some fluid which would remain and cause collapse of the lungs. In experimentation on animals I was unable to find any liquid that was safe to use and which would remain for any length of time in the chest cavity without being absorbed or causing suppuration. I found that cacao butter was the most effective, as it would remain in the pleural cavity of a dog and cause compression, but I never felt warranted in injecting it into a patient. All other substances which I used were ineffectual.

In the spring of 1898 Dr. J. B Murphy, of Chicago, read a paper before the American Medical Association, in Denver, on "The Surgery of the Lungs," in which he reported a number of cases of phthisis which had shown marked improvement from injections of nitrogen gas into the pleural cavity. He found that the pleural cavity could be filled with nitrogen gas, and that this gas would remain for a number of weeks or months without being absorbed In cases of pneumothorax the composition of the air contained in the pleural cavity, as subjected to analysis by Dory, Bouveret, Le Conte, Ewald, and others, seems to differ little in composition from the outside atmosphere. If, however, the pneumothorax becomes closed, the oxygen steadily diminishes and finally disappears, the carbon dioxide decreases, and the last element to disappear is the nitrogen. This apparently proves theoretically the claim of Dr. Murphy. It has been said that Prof. Carlo Forlanini has used nitrogen-gas injections into the pleural cavity for pulmonary tuberculosis for the past ten years, but I am unable to ascertain that he more than suggested its use before the International Medical Congress in Rome, in 1894, and that he had no practical experience in its use.

After reading Dr. Murphy's article I decided to give this treatment a thorough test, and I have made these injections during the past two years in eighteen selected cases; and it is to the report of the results which I obtained and the uses and limitations of this method of treatment that I will ask your attention for a few moments more. I might say here that the longer I employed this method the more favorably I became impressed with its efficacy in certain cases. If one intends to use this treatment there are two things which it is advisable to do· First, to obtain the special apparatus as recommended by Dr. Murphy for injecting the gas (see cut); second, to see that the nitrogen gas used is pure. Most of the nitrogen gas on the market is nothing but compressed air

Operation.—The gas is best injected with the patient sitting in bed, although I have performed the injection with the patient sitting in a chair At the point where the needle is to be inserted the chest is sterilized by the ordinary method The point of the insertion of the needle varies somewhat in each individual. Personally I have obtained the best result by inserting the needle behind the posterior axillary line in about the eighth interspace, although Dr Murphy generally makes the insertion in the fifth interspace in the anterior axillary line. If it be a middle or lower lobed tuberculosis the injection should be made over the upper lobe, preferably in the third interspace just outside the mammary line. Chloride of ethyl may be used as a local anæsthetic. The trocar attached to the rubber tube connected with the gas retort is easily inserted. It gives hardly more pain than an ordinary hypodermic injection. The stylet in the trocar should be withdrawn when the rib is reached. The gas should now be turned on. The trocar should then be pushed in close to the margin of the rib.

[1] Berliner klinische Wochenschrift, May 22, 1899

[1] British Medical Journal, October 22, 1898

When the parietal pleura is punctured the trocar advances rapidly and the gas is seen to flow by the dropping of the upper portion of the gas retort, first slowly and then more rapidly. If the gas does not flow readily at first the trocar is moved back and forth, and on the least indication of the gas flowing the trocar should be held still. If adhesions are present the gas will not flow; the trocar should then be removed and inserted in the same manner in another place. When the gas is running freely into the pleural cavity it is found that from one to five cubic inches will pass in with each inspiration. The quantity of gas to be injected will vary considerably, and will range from fifty to two hundred cubic inches. The amount to be injected will vary with each case according to the dyspnœa, distress, irregularity of the heart, and displacement of the mediastinal contents. My experience has been that people vary a good deal in the way in which they take the injection. I have never seen any bad results whatever follow the injection. If the patient's discomfort should suddenly become very great, the current of gas can at once be reversed by raising the cylinder and withdrawing part or all of the gas from the chest. Having injected as much gas as possible, the trocar should be withdrawn and the puncture covered with cotton wet with collodion, and a firm compress placed over the puncture and a broad band of adhesive plaster over the compress.

If one hundred or more cubic inches of the gas have been injected, the respiratory sounds upon the injected side will be completely suppressed, the heart will be displaced, and if the injection is on the left side the apex will be carried as far as the median line. It is astonishing how few unpleasant effects follow these injections. I have injected a number of times two hundred cubic inches of nitrogen gas, completely compressing the lung and markedly displacing the heart, and had the patient in a few minutes put on his coat and walk about without any apparent discomfort. The respirations are always increased after the injections. The pulse rate is generally lowered, and the patients complain often of a "tightness" about the chest. One of the earlier cases I injected presented peculiar symptoms from the gas leaking through the trocar puncture and filling the subcutaneous tissue of the chest. This subcutaneous emphysema persisted for a number of days, and the patient showed constitutional effects of the gas by an excited and talkative condition which lasted for about twelve hours after the injection. That the gas fills the chest cavity can be proven not only from a physical examination of the lungs, but also by the placing of the heart, and, as I have done a number of times, by examining the patient with the *x*-ray after the injection. The radiograph shows conclusively the lung compressed, the diaphragm immovable, and the heart displaced. My experience leads me to believe that, to obtain any marked and permanently beneficial results, the lungs should be kept quiescent for from three to six months or even longer. The more gas injected the longer it will remain and the less frequent need be the injection. I have seen the gas in a number of cases remain three or four months without any apparent diminution. In other cases the gas will have to be injected at the end of from four to six weeks. Physical examination can easily decide when a second injection is necessary.

One of the most constant effects noted after injections is that there will be a marked increase in the expectoration during the first twenty-four hours, sometimes an increase of tenfold over the ordinary amount expectorated per day. After the first few days expectoration diminishes rapidly. The gain in weight of the patients is so constant and often so excessive after the injections that one is astonished and almost at a loss sufficiently to account for it. I have not noticed any sudden fall of temperature following the injections as reported by Dr. Lemke and Dr. Murphy, of Chicago. In many cases the temperature gradually declines, but it did not seem to be due to the effect of the injection. Upon the temperature the injections seemed to have less effect than upon any of the other constitutional symptoms. In one case the patient was suddenly seized with a severe stitch-like pain on the affected side, which as suddenly disappeared; this was probably due to tearing of adhesions by the gas. Night sweats were unaffected except in so far as they gradually disappeared as the patient's general condition improved. In looking over the carefully kept record of my cases I am impressed with this thing, viz., the marked improvement in the subjective symptoms following the injections, such as diminution in the cough and expectoration, rapid gain in weight and strength, stoppage of hemorrhages and night sweats, and improved appetite.

It does not seem to me, however, that the physical changes noted in the lungs show such an improvement as the subjective symptoms would suggest. When the gas is absorbed and the lung can once more be examined, in the majority of cases no greatly marked improvement of the lesion can be noted. I am convinced that if permanent results are to be expected the chest cavity must be kept filled with gas for six months at least. The two cases that gave me the most satisfactory results were watched carefully for four months, and the compression was kept up by repeated injections.

Dr. Murphy, in his original article, makes no mention of the effects of these injections upon pulmonary hemorrhages. I was first tempted to use the injections in these cases on theoretical grounds. The results astonished me. Hemorrhages of all varieties, from the daily spitting of blood-streaked sputum to profuse hæmoptyses, were at once controlled, and in almost all the cases there was no return of the bleeding. These results were especially astonishing in one or two cases of persistent bleeding in which it was impossible to control this by any of the usual means such as absolute quiet and rest with hypodermics of morphine every four hours. The hemorrhages stopped at once after the injections. It is difficult to explain why these injections should have such a pronounced effect on pulmonary hemorrhages, but that they do I am thoroughly convinced.

Kind of Cases Benefited.—Theoretically, cases of apical unilobar tuberculosis in the early stages with lungs free from adhesions would be the ones in which we should expect the best results from this treatment. These are the cases in which the most compression is possible. The localized cavity at the apex is another class of cases which presents favorable conditions for treatment. One of the most remarkable results which I obtained was in Case III., in which a slight pulmonary lesion of the apex was complicated by a general tuberculous pleurisy. The separation of the two pleural surfaces at once cured the pleurisy and relieved marked constitutional symptoms.

The more I have used the gas the more I have been tempted to use the injections in advanced and apparently hopeless cases. I find that it relieves the patient and stops many of the distressing symptoms. The only objection to its use that practical experience has taught me is that these injections cannot be made in many cases on account of the inability to force the nitrogen gas into the pleural cavity on account of the adhesions. My experience has been somewhat different from Dr. Murphy's in this respect. He has been able to inject into the pleural cavity of almost all of his patients. In a number of cases apparently favor-

able for treatment I have had to abandon the method on account of adhesions. In no way except by practical test can we discover whether there are enough adhesions to make the method of treatment impracticable.

Analysis of Cases Injected.—

1. Total number of cases. Eighteen.
2. For pulmonary hemorrhages. Eight cases.
3. For effect on lungs. Ten cases.
4. Effects on hemorrhage. Stopped at once.
5. Effect on lung condition. In the majority of cases the physical signs remained the same except that râles diminished or disappeared. Only one case showed a marked improvement. Pleurisy was controlled at once.
6. Number of cases gained in weight. Sixteen.
7. Number of cases lost in weight. None.
8. Average gain in weight per patient. Seven and one-half pounds.
9. Number of injections given. Twenty-nine.
10. Average amount of gas injected. 107½ c.c.
11. Number of cases in which improvement was noted. In:
    (1) Cough, thirteen cases; three slightly and temporarily.
    (2) Expectoration, eleven cases.
    (3) Fever, four cases.
12. Number of cases during the past year in which the injections were tried and failed owing to the inability to introduce the gas (adhesions, etc.), eight.

Remarks on Treatment.—I am convinced that intrapleural injections of nitrogen gas will have a dermanent place in the treatment of pulmonary tuberculosis.

1. It is a treatment that has a future; I would advise its more extended use; only in this way can we ascertain the kinds of cases to which it is best applied.
2. I have never seen any bad results or even unpleasant effects following the injections.
3. I have seen no cases result in absolute cure of the disease.
4. I have certainly seen the apparent arrest of the disease in two cases, and the disappearance of such constitutional symptoms as expectoration, fever, and cough in a number more. Sufficient time has not yet elapsed to say whether in even the most favorable cases the activity of the disease may not return.
5. The local improvement is not so apparent as the constitutional.
6. A marked gain in weight is found in every case injected. This is so universal as to be astonishing, especially as the cases have had no other treatment and many of them have been in hospital wards and under anti-hygienic surroundings; yet the gain in weight has followed almost immediately after injections, and when a patient had been losing weight before the injections he suddenly began to gain. It is very difficult to explain this effect, except by the marked effect upon the pulmonary lesion.
7. That this method of treatment will stop pulmonary hemorrhages I am thoroughly convinced. I have never seen it fail even in one of the most desperate cases upon which it was tried. If these nitrogen-gas injections have no other place in the treatment of pulmonary tuberculosis, it seems to me that their ability to arrest pulmonary hemorrhage gives them a place which no other method we have at the present time can occupy.

Synopsis of Cases Injected with Nitrogen Gas for Pulmonary Hemorrhage.—

Case I.—John N——, aged thirty-eight years. Duration of disease, three years. Pulmonary condition, consolidation with fibroid changes at both apices—moderate at left, and involving entire upper lobe on right side. Number of hemorrhages before injection, continuous for eight days. Extent of hemorrhage, very severe. Number of hemorrhages after injection, none. Number of injections, one. Amount of gas injected, 193 c.c. Weight before injection, one hundred and four pounds. Weight after injection, one hundred and eighteen pounds (end of four months). Effect of injections on (1) cough, diminished; (2) expectoration, decreased; (3) fever, temperature normal after three weeks.

Remarks: In 1898 the patient was injected for his general condition once. The improvement in weight, etc., followed this injection. In 1899 the injection was given to stop the most profuse hemorrhages I have ever seen.

Case II.—John F——, aged thirty-four years. Duration of disease, five months. Pulmonary condition, consolidation involving the upper portion of the left lung with large and small râles. Number of hemorrhages before injection, many. Extent of hemorrhage, slight; sputum streaked with blood for a number of months. Number of hemorrhages after injection, none. Number of injections, two. Amount of gas injected (approximate), 114 c.c. and 80 c.c. Weight before injection, one hundred and forty-seven pounds. Weight after injection, one hundred and fifty-seven pounds (two months after). Effect of injections on (1) cough, diminished; (2) expectoration, none; (3) fever, none.

Remarks: This case shows the favorable effects of the injections on continuous bleedings, also at the same time on the pulmonary condition and the patient's general health.

Case III.—William H——, aged twenty-four years. Duration of disease, five months. Pulmonary condition, very slight consolidation localized at the right apex. Number of hemorrhages before injection, two severe; constant spitting of blood-streaked sputum. Extent of hemorrhage, severe. Number of hemorrhages after injection, none; blood-stained sputum stopped within six hours. Number of injections, one. Amount of gas injected (approximate), 120 c.c. Weight before injection, one hundred and fifty-four pounds. Weight after injection, same (only seen two weeks). Effect of injections on (1) cough, decreased; (2) expectoration, decreased; (3) fever, had none.

Remarks: Stopped at once moderate bleeding that had lasted for eight days and had resisted ordinary treatment.

Case IV.—Adam S——, aged thirty-four years. Duration of disease, two years ten months. Pulmonary condition, incipient involvement of right apex and left upper lobe. Number of hemorrhages before injection, repeated hæmoptyses. Extent of hemorrhage, slight but continuous. Number of hemorrhages after injection, none. Number of injections, three. Amount of gas injected (approximate), 80 c.c. (average). Weight before injection, one hundred and fifty-four pounds. Weight after injection, one hundred and fifty-eight and one-half pounds. Effect of injections on (1) cough, decreased; (2) expectoration, decreased; (3) fever, had none.

Remarks: A number of small injections were necessary to control the bleedings completely; when stopped they remained so. The patient had had slight but continuous bleedings for a number of months.

Case V.—John L——, aged forty-three years. Pulmonary condition, consolidation and softening at upper portion of left lung; beginning changes at right apex. Number of hemorrhages before injection, numerous. Extent of hemorrhage, slight. Number of hemorrhages after injection, none. Number of injections, one. Amount of gas injected (approximate), 110 c.c. Weight before injection, one hundred and

sixty-two pounds. Weight after injection, one hundred and seventy-three pounds. Effect of injections on (1) cough, none; (2) expectoration, none; (3) fever, none.

Remarks: The patient's general condition is improved but not his pulmonary. He had laryngeal tuberculosis, which was unaffected.

Case VI.—Harry A——, aged twenty years. Duration of disease, more than a year. Pulmonary condition, consolidation at right apex; left upper and middle lobe also affected. Number of hemorrhages before injection, numerous. Extent of hemorrhage, severe. Number of hemorrhages after injection, none. Number of injections, one. Amount of gas injected, 135 c.c. Weight before injection, one hundred and thirty-eight pounds. Weight after injection, one hundred and thirty-six pounds. Effect of injections on (1) cough, none; (2) expectoration, none; (3) fever, none.

Remarks: The injections had no effect on the progress of the disease, but stopped at once the hemorrhages.

Case VII.—Mrs. C. A——, aged thirty-eight years, Duration of disease, about sixteen months. Pulmonary condition, consolidation and small cavity at left apex; slight changes at right apex. Number of hemorrhages before injection, six. Extent of hemorrhage, two severe. Number of hemorrhages after injection, none. Number of injections, one. Amount of gas injected (approximate), 60 c.c. Weight before injection, one hundred and eighteen pounds. Weight after injection, one hundred and eighteen pounds. Effect of injections on (1) cough, none; (2) expectoration, none; (3) fever, had none.

Remarks: Owing to adhesions only a small quantity of gas could be injected. The gas remained in the pleural cavity only seven days.

Case VIII.—Adeline C——, aged twenty years. Duration of disease, six years intermittently. Pulmonary condition, infiltration of right upper lobe and left apex. Number of hemorrhages before injection, numerous. Extent of hemorrhage, severe. Number of hemorrhages after injection, one after first injection. Number of injections, two. Amount of gas injected (approximate), 120 c.c., 110 c.c. Weight before injection, one hundred and thirty-seven pounds. Weight after injection, one hundred and fifty-one pounds. Effect of injections on (1) cough, greatly decreased; (2) expectoration, greatly decreased; (3) fever, normal temperature after a time.

Remarks: Although the injections were given for the hemorrhages, there was a marked improvement in the patient's general and pulmonary condition.

Synopsis of Cases Injected with Nitrogen Gas for Effect on the Lungs.—

Case I.—Stella W——, aged nineteen years. Duration of disease, four weeks. Pulmonary condition, slight consolidation at left apex; fine crepitations all over left chest. Number of injections, one. Amount of gas injected, 160 c.c. Weight before injection, one hundred and three pounds. Weight after injection, one hundred and fourteen pounds (end of eight weeks). Effect of injections on (1) cough, marked diminution; (2) expectoration, decreased; (3) fever, dropped from 105° to 101° in the first twenty-four hours; (4) general condition, greatly improved. Effects of injections on pulmonary condition: Fine crepitations (pleuritic) at once disappeared; in eight weeks the patient was under observation consolidation remained the same.

Remarks: This case was at first supposed to be one of acute pulmonary tuberculosis, but the results show that the pulmonary changes were only in the pleura.

Case II.—Mary B——, aged thirty-three years. Duration of the disease, nine months. Pulmonary condition, consolidation of left lung, with râles, from apex to middle of scapula. Number of injections, two. Amount of gas injected, 58 c.c. and 70 c.c. Length of time gas remained in chest, two months and over. Weight before injections, one hundred and twenty-eight pounds. Weight after injections, one hundred and forty-one pounds (end of two months). Effect of injections on (1) cough, none; (2) expectoration, none; (3) fever, after ten days reached normal. Effects of injections on pulmonary condition: consolidation not affected; râles disappeared.

Remarks: There was a marked gain in weight.

Case III.—Owen L——, aged thirty-four years. Duration of disease, not known. Pulmonary condition, evidences of consolidation over middle of left lung, with crepitations and râles below. Number of injections, one. Amount of gas injected, 87 c.c. Length of time gas remained in chest, while under observation. Weight before injections, one hundred and forty-six pounds. Weight after injections, one hundred and forty-three pounds. Effect of injections on (1) cough, slight improvement; (2) expectoration, none; (3) fever, marked diminution; (4) general condition, improved. Effects of injections on pulmonary conditions, none.

Remarks: This case was supposed at first to be lobar pneumonia; later it was diagnosed as localized tuberculosis with accompanying tuberculous pleurisy.

Case IV.—Joseph F——, aged thirty-four years, Duration of disease, twenty months. Pulmonary condition, chronic tuberculous changes at both apices, left extensively involved; no softening. Number of injections, two. Amount of gas injected, 130 c.c. and 130 c.c. Length of time gas remained in chest, two months. Weight before injections, one hundred and fifty-seven pounds. Weight after injections, one hundred and sixty-five pounds. Effect of injections on (1) cough, greatly improved; (2) expectoration, first increased, then diminished; (3) fever, none; (4) general condition, unchanged. Effects of injections on pulmonary condition, none.

Remarks: Ten days after first injection the patient's weight increased eight pounds and remained the same eight months afterward.

Case V.—Christian M——, aged forty-three years. Duration of disease, one year. Pulmonary condition, consolidation of upper lobe of right lung with infiltration and some softening. Number of injections, one. Amount of gas injected, 150 c.c. Length of time gas remained in chest, six weeks. Weight before injection, one hundred and twenty-nine pounds. Weight after injection, one hundred and thirty-five pounds. Effect of injections on (1) cough, marked diminution; (2) expectoration, disappeared; (3) fever, none; (4) general condition, improved. Effects of injections on pulmonary condition, none.

Remarks: The patient attended to his work with the gas in the pleural cavity.

Case VI.—Eugene P——, aged twenty-six years. Duration of disease, one year. Pulmonary condition, very slight involvement of right upper lobe; pleuritic thickening in lower lobe of left lung. Number of injections, two. Amount of gas injected, not noted. Length of time gas remained in chest, about six days each injection. Weight after injections, gained one and one-half pounds. Effect of injections on (1) cough, slight improvement; (2) expectoration, slight improvement; (3) fever, had none. Effects of injections on pulmonary condition, none.

Remarks: After the first injection most of the gas escaped into the cellular tissue, causing intoxication. After the second injection the gas had to be withdrawn owing to continued dyspnœa.

Case VII.—Bertha W——, aged nineteen years. Duration of disease, five months. Pulmonary condi-

tion, advanced involvement of upper portion of right lung; cavity. Number of injections, three. Amount of gas injected, each time about 60 c.c. Length of time gas remained in chest, one month. Weight before injections, ninety-nine pounds. Weight after injections, one hundred and five pounds. Effect of injections on (1) cough, none; (2) expectoration, none; (3) fever, none; (4) general condition, none. Effects of injections on pulmonary condition, improved while gas remained in chest.

Remarks: Injections given to close up cavity were successful while the gas remained, but the gas appeared to be quickly absorbed.

Case VIII.—Mrs. C. Z——, aged thirty-eight years. Duration of disease, fourteen months. Pulmonary condition, cavity at left apex, surrounded by fibrous tissue with adhesions. Number of injections, two. Amount of gas injected, not noted. Length of time gas remained in chest, six weeks. Weight before injection, one hundred and fifteen pounds. Weight after injections, one hundred and eighteen pounds. Effect of injections on (1) cough, lessened for a time only; (2) expectoration, lessened for a time only, (3) fever, diminished temporarily; (4) general condition, slightly improved. Effects of injections on pulmonary condition, unable to close cavity on account of adhesions.

Remarks: Injection was made under *x*-ray, results were unsatisfactory.

Case IX. — Leonard C——, aged forty years. Duration of disease, about two years. Pulmonary condition, cavity with softening at upper portion of left lung; slight infiltration at right apex. Number of injections, two. Amount of gas injected, 100 c.c. and 110 c.c. Weight before injections, one hundred and thirty-eight pounds. Weight after injections, one hundred and forty-four pounds. Effect of injections on (1) cough, lessened at first, then increased; (2) expectoration, lessened at first; (3) fever, none; (4) general condition, improved. Effects of injections on pulmonary condition, unable to close cavity on account of dense adhesions.

Remarks: During first injection, some adhesions were torn as evinced by sudden sharp pain in the side.

Case X.—Miss H——, aged twenty-two years. Duration of disease, two months. Pulmonary condition, slight consolidation at right apex. Number of injections, one. Amount of gas injected, 171 c.c. Length of time gas remained in chest, one month. Weight before injections, one hundred and twenty-two pounds. Weight after injections, one hundred and thirty-one pounds. Effect of injections on (1) cough, decreased; (2) expectoration, decreased; (3) fever, had none; (4) general condition, improved. Effects of injections on pulmonary condition, none.

The Vitality of Certain Pathogenic Micro-organisms in the Juices of the Organs of Healthy Animals. — Andrea Ciaccio from experimentation concludes: (1) that in the extracts of organs kept at a temperature of 37° C. (98.6° F.) micro-organisms were able to develop; (2) that the juices of the brain, liver, heart, spleen, lungs, and muscles of guinea-pigs and sheep possess antibacterial properties, quite independently of temperature; (3) muscular tissue in especial possesses bactericidal properties. The value of the administration of raw meat in certain affections is well known, as, for instance, in tuberculosis, (4) the addition of certain other substances to the extracted juices appears to influence their properties; for instance, dog's serum and sodium chloride increase their bactericidal powers. — *Rassegna Internazionale della Medicina Moderna*, August 15, 1900.

ELECTRICITY IN GYNÆCOLOGY AND THE PRESENT RELUCTANCE OF GYNÆCOLOGISTS TO USE ELECTRICITY.[1]

By ROBERT NEWMAN, M.D.,

NEW YORK,

CONSULTING SURGEON TO HACKENSACK AND BAYONNE HOSPITALS, N. J., M'DONOUGH MEMORIAL HOSPITAL, GERMAN DISPENSARY, WEST SIDE, N. Y.; FORMERLY PROSECTOR, LONG ISLAND COLLEGE HOSPITAL; CORRESPONDING MEMBER OF THE GYNÆCOLOGICAL SOCIETY, BOSTON, ETC.

In looking over the bibliography of the subject an abundant evidence of the successful therapeutic use of electricity in almost every disease peculiar to woman is found in text-books, addresses, and papers by the best-known gynæcologists. The list includes particularly:

Uterus—Abrasion of the os uteri, stenosis of the os and uterine canal, endometritis, cervical catarrh, amenorrhœa, dysmenorrhœa, menorrhagia, metrorrhagia, flexions, subinvolution, hyperplasia, fibroid neoplasm, prolapsus, procidentia, polypi, and carcinoma. Tumors—Fibroid, ovarian. Appendages—oöphoritis, cysts, salpingitis, pyosalpinx, and hæmatosalpinx. Pelvis—adhesions, cellulitis, pelvic hæmatoma, hæmatocele. Urethra — stricture. Bladder—neuroses, papilloma, benign and malignant tumors. Rectum—stricture. Vulva — growth, cysts. Extra-uterine pregnancy, etc.

The successful treatment by gynæcologists must be a fact, if they tell it themselves and have it recorded in the literature on the subject. Naturally the question arises, why the same gentlemen in a body by a vote denounce electro-therapeutics as a failure. An investigation for facts and truth may not be pleasant, and it is not my desire to elicit unpleasantness hence let us cover with professional love all differences. Only one inquiry of the writer may be noted here, which gives one of the many reasons. One of the staff of a special hospital was asked why his colleagues had denounced the use of electricity in gynæcology, while there were recorded so many successes. He answered: "We have an excellent electro-therapeutist on the hospital staff, and cases which were referred to him he often did not cure. On the contrary, we often found adhesions when laparatomy was performed after an electrical treatment."

The electro-therapeutist in question then was interviewed and said: "There is some truth in the former statement. I have cured cases and have had success with electro-therapeutics, but some cases are either tedious or incurable. Next I had no choice in the selection of the patients suitable for a successful treatment. Some patients not wanted by the operating staff nor by myself were referred to me, and nolens volens I had to treat them, even though I knew they were not suitable for a successful treatment by electricity."

The very same thing happens to other electro-therapeutists on the staff of other hospitals. They have to treat unsuitable cases against their wishes, and no protest changes the matter, but even then often they succeed. Concerning adhesions, our ex-president, Dr. Lapthorn Smith, remarked once in a discussion: "I think it is unjust and unfair for my friend Dr. Joseph Price and others to lay all the blame of adhesions on electricity, when they know as well as I do that these complications are met with in cases which have never been touched with electricity, while, on the contrary, they know that cases which have been treated for a year with electricity were found at the operation to be absolutely free from adhesion."

Injudicious treatment and particularly too strong a current may cause adhesions, but the therapeutic agent

[1] Read at the meeting of the American Electro-Therapeutic Association, September 26, 1900, held at the Academy of Medicine, New York.

cannot be held responsible for the mistakes of the operator. Mistakes of doctors and druggists may have killed people, but it never has been known that opium or any other drug had been condemned on that account.

The writer has treated successfully with electricity most of the diseases above enumerated. There was a series of cases of prolapsus uteri, in some of which the uterus was outside and entirely irreducible. The high-tension current cured in every case, and it could be seen how the electricity caused contraction and diminished the size of the organ, so that it was reduced and pulled back to its normal place without the use even of the hand, and solely by the action of the electric current. But let us adhere entirely to our text, the use of the continuous current.

In many cases electrolysis has been used, which means that the galvanic current is applied in such a manner that by chemical decomposition compound bodies or salts are reduced to their component parts. Thereby the current reabsorbs pathological formations not alone polar but interpolar, and the fact explains also how we cause the reabsorption of fibroids.

Fibroid tumors of the uterus may be peritoneal, interstitial, or submucous. Nobody would advocate the use of electricity in peritoneal fibroids, and it seems that many operations for them are unnecessary, as we often find on autopsies large peritoneal fibroids, which in life never had troubled the bearer. With the other two varieties the writer has had invariable successes.

Formerly needles were used, partly as galvano-puncture under strong currents. Dr. J. N. Freeman, of Brooklyn, read a paper on January 20, 1885, before the Medical Society of Kings County, in which he reported three successful cases of fibroid tumors treated by galvano-puncture. Freeman operated, with the patient under an anæsthetic, with needles and with strong currents. Freeman's memory as a pioneer in this line should go down to posterity. During his life the Brooklyn profession could not comprehend his arduous work and success. Almost at the same time our lamented honorary member, G. Apostoli, in establishing his method of treatment by electricity, labored assiduously in Europe and America, was successful, and made many friends, but also met bitter opposition and was more abused than appreciated.

Menière in Paris with six cases, and J. T. Everett, Clyde, Pa.,[1] with seventeen cases, came next, and were followed by Franklin Martin,[2] W. E. Stevenson,[3] E. Cutter,[4] Semeleder,[5] A. H. Buckmaster, W. F. Hutchinson, A. Lapthorn Smith,[6] J. H. Kellogg,[7] Massey, Schavoir, and many others too numerous to mention. During a discussion on "Fibroids," at the last meeting of the British Medical Association, our honorary fellow, Dr. Skene Keith, said he believed in and practised Apostoli's method.[8]

The art in applying electrolysis successfully in gynæcology consists in: (1) using the correct strength of the galvanic current; (2) applying the poles at the right place; (3) selecting the size and material of the electrodes; (4) timing the duration and intervals of the séances.

Electrolysis applied with a mild current will cause absorption only, while a strong current will burn, cauterize, and even destroy tissues. Therefore the operator must know what effect he wishes to produce, and then graduate the strength of the current accordingly. Very strong currents have been used, but the writer has always advocated weak currents, and has been successful in his cases. This is a practical point in the argument, but his theoretical reasons are that strong currents may cause serious inflammations and destruction of healthy tissues while the current traverses living tissues in all directions, interpolar, but mostly polar. It has been shown in a series of experiments that currents of great electro-motive force became uncontrollable when traversing animal tissues. The writer has always succeeded better with mild currents, and prefers to use the mild currents a longer time if necessary. By mild currents is understood a strength which can be tolerated by the patient without being painful. A fixed amount of amperage cannot be stated. Applying the correct pole in the right place means particularly using the positive pole for stopping hemorrhages, while the negative pole will absorb the fibroid tissues.

In selecting the material and size of electrode the writer does not use needles, but generally makes his way into the uterus with a blunt platinum sound, and always pushes this by degrees into the tumor, sometimes to the depth of eight and ten inches. For the abdominal electrode nothing suits better than pottery clay, which, however, must be kept warm, smooth, and moist; its size should be about twelve by twenty inches.

The duration and intervals of the séances must be regulated according to indications. The time for a cure of a fibroid tumor cannot be exactly stated, but depends on the nature and size of the tumor, the complications, and the constitution and pluck of the patient.

Interstitial tumors may be either diffused in the uterus, or circumscribed in one locality. If the latter, which is usually the case, the electric current is directed toward the tumor. These tumors are more or less adherent to the wall of the uterus, and often they are encapsulated. The treatment by electrolysis consists in possible absorption of the tumor, or at least in making it smaller, cutting off its nutrition, and leaving it small in a dormant state, when it will do no harm. Sometimes it may do good to rupture the capsule. Then one of two things may happen. The tumor may slough off, which takes some time, and then the electric current may do harm, and great care should be taken to prevent sepsis, and to keep up the vitality of the patient. In one case, in which the tumor was very large and of eleven years' standing, the writer operated in the way just described during more than three months, using the blunt platinum electrode. The patient was very weak and often in collapse, but finally made a good recovery. The diagnosis was first made by Dr. E. M. Moore, of Rochester. Another patient was brought to the writer's office, who had lost so much blood by active hemorrhage that her life was in danger. Therefore she had to remain at his house, as she could not be moved, and be treated for the hemorrhage, as she was almost bloodless. She made a good recovery. She was heard from twelve years afterward, when she was alive and well.

Sometimes after the capsule has been ruptured the tumor may be pulled out of the uterus, somewhat like enucleation, and if the adhesion is small and pedunculated the tumor may be removed in its entirety at the pedicle with the galvano-cautery platinum wire, or with an écraseur.

Submucous tumors are almost always hanging by a pedicle in the uterine cavity and cause the most trouble by hemorrhage. The best treatment is the removal of the tumor by galvano-cautery under antiseptic precautions.

The writer has always treated his cases of fibroid tumor successfully by electricity, and never has lost a case. Sometimes the tumor has not entirely disappeared, but was small and lay dormant, without causing any trouble or inconvenience.

Now a few words as to the diagnosis of these cases, which has been always verified by good authorities, or made before the patient came under treatment. In some cases I have selected a good surgeon of unquestionable standing, who was believed to be prejudiced against electricity, to examine the patient, confirm the diagnosis, and locate the fibroid tumor. The same surgeon was again invited to examine the same patient after the electric treatment, and was then obliged to acknowledge that the tumor could no longer be found, and that therefore the electrolysis must have caused its absorption.

Some may ask, why these cases have not been published before. My answer is that I have had my share of abuse for praising electrolysis, and therefore would leave some criticism for others; besides, I did not wish to encroach so far on the work and glory of the gynæcologists. Other diseases of the uterus have been treated with various results. Is there a man who can assert that he has cured all cases of uterine catarrh by any routine? Ovarian tumors cannot be expected to yield under any electric treatment, because they are mostly multilocular cysts, and the piercing of the tumor by a needle may cause peritonitis and adhesions.

Pelvic cellulitis may be cured by electrolysis judiciously and carefully applied. The writer has had among other cases a very bad one, with adhesions which held the uterus retroflexed and adherent in the peritoneal cavity. A consulting gynæcologist confirmed the diagnosis and considered the adhesions permanent. The writer treated the case by persistent electrolysis, using the negative pole in Douglas' culde-sac, pushing the instrument backward and upward. The adhesions were thereby removed and the patient was cured. This was eighteen years ago, and the patient was seen only recently and was found to have remained well since that time. Several other similar cases are in the writer's notes, but none with such bad prognosis.

Peritonitis has been cured by Dr. W. E. Ford, of Utica.[1]

In peri-uterine hæmatocele Apostoli[2] has had excellent results by means of negative galvanic puncture. He says that it is applicable alike to hæmatocele, abscess, fibromata, interstitial myomata, and extra-uterine cysts.

Strictures of the female urethra are rare, but they occur occasionally and are readily cured by electrolysis. The writer has reported some of his cases.[3]

Oöphoritis and salpingitis are intimately connected, say our modern authors. Cases appear in different stages; some are very difficult to manage and no treatment will positively cure. I have had some cures by electrolysis, having notes of cases treated from 1872 to 1887. One acute case was treated successfully in five séances. I have generally used the negative metal electrode in the vagina, and a positive pad on the abdomen over the ovary.

In one case in private practice the patient, who was very poor, had been treated medically, the case being regarded almost hopeless. Friends applied for her admission to hospital, and in every institution the surgeon in charge insisted on laparotomy and removal of the uterus and appendages. The writer objected to such harsh measures, and after quieting the patient with morphine took her to a hospital out of town to which he is attached as consulting surgeon. There the patient was curetted, drainage was established, and she made a good recovery. I have seen her only very recently. No electricity was used.

In bladder neuroses, papilloma, and other tumors, electrolysis, after the diagnosis has been made by the cystoscope, is certainly indicated. The writer has removed papillomata with the galvano-cautery, and tumors by means of electrolysis with needles. A paper in which cases of this kind were reported was read before this association in Chicago in 1893.[1]

Strictures of the rectum are more successfully treated by electrolysis than by any other method. The writer has had considerable experience with cases of stricture of the rectum, and read a paper on this subject before the American Medical Association at Newport in 1889.[2] Most of the cases were successfully treated; in some recovery could not be expected. One woman, who subsequently underwent a surgical operation in a hospital, died soon afterward.

The vulva has sometimes growths or cysts which can be removed either by surgical operation or by electrolysis.

In extra-uterine pregnancy the profession is divided as to the best treatment, and some surgeons prefer laparotomy. However, we have reports of successful treatment by electricity by eminent men, of whom the following may be mentioned: Drs. A. D. Rockwell,[3] E. G. Landes,[4] Nathan Bozeman,[5] H. J. Garrigues,[6] W. Goodell,[7] Eli Van de Warker,[8] Reeve, T. Lusk,[9] A. H. Buckmaster,[10] Matthews Duncan,[11] Percy Boulton,[12] and W. E. Stephenson.[13] The *modus operandi* differs, but it seems electrolysis is mostly used. One method is to have one pole in the vagina or rectum, the other pole on the abdomen.

Basing my conclusion on my own experience and on reports contained in the literature on the subject, I may say that we obtain better results from treatment by electricity than by other means, and the reluctance of gynæcologists to apply electricity, or at least to recommend it, has not been explained.

We need a means for a better education of the medical men in electro-therapeutics, and should strive to see the establishment in New York of a school, laboratory, hospital, and clinic in electro-therapeutics.

A CURE OF A CASE OF HYPERTROPHIC ALCOHOLIC CIRRHOSIS OF THE LIVER, WITH REMARKS.*

By M LUZZATTO, M.D.,
NEW YORK.

G. A——, aged fifty-five years, a carpenter by occupation. Family history good; his parents both died of old age. Past history: Twenty-six years ago, while residing in a malarial district, he developed intermittent fever, from which he suffered at times for a period of ten months. Eight years later he had another attack of malaria, lasting for about one month. With these exceptions he has always felt well, although since boyhood he has been subject to attacks of nosebleed, which were finally controlled by venesection practised every four months. The patient's habits, however, have not been good, as since the age of sev-

* Read before the Italian Medical Society of New York, June 27, 1900.

enteen years he has been constantly increasing his amount of stimulants. When a boy of seventeen he drank two, three, or four glasses of wine a day, but when over twenty he increased this amount, and on Sunday was in the habit of taking two quarts of wine; when thirty-two he was taking twelve drinks of whiskey and three or four pints of beer every day. At the age of fifty years, after eighteen years of hard drinking, during which time he ate very little and worked very hard, he was obliged to give up drinking spirits, as it seemed to produce attacks of dyspnœa and vomiting.

About September 15, 1894, he began to feel bad, and two months later (November 9, 1894) he consulted me about his condition. He then complained of difficulty in breathing, sticking pains in the right side of the chest low down, and a tenderness over the right side of the abdomen. On examination I found that he had a temperature of 100° F., a pulse of 80, hydrothorax on both sides, and a beginning pulmonary œdema. He also had ascites and a reducible hernia on both sides, which could in no way be retained within the abdominal cavity, even with the truss. His abdomen measured thirteen inches from the ensiform cartilage to the pubis; thirty-five and one-half inches in circumference at the level of the umbilicus, and thirty-seven and one-half inches at the point of its maximum, which was about two inches above the umbilicus. The abdominal veins (subcutaneous collateral circle) were very much enlarged. A diagnosis of alcoholic hypertrophic cirrhosis of the liver was made.

Treatment: The patient was put on a milk diet of four and one-half pints a day. His condition, however, grew rapidly worse, and the ascites increased. A consultation with Dr. A. Loomis was accordingly held, and the diagnosis was confirmed. After the consultation it was decided to put the patient on the following powders: Calomel, gr. i.; pulv. digitalis, gr. i., pulv. squill, gr. iii.; to be taken four times a day. In addition to which a teaspoonful of Epsom salts was given every morning, and a milk diet was instituted. The condition of the patient at the beginning of the treatment was as follows:

November 26, 1894: Milk taken daily, 2,250 c.c.; urine passed, 500 c.c. Abdominal measurements: vertical 13 inches; circumferences—umbilical, 35½ inches; at its maximum, 37½ inches. Pulse, 80; temperature, morning 100°, evening 101° F.

After three days of this treatment the patient could no longer endure a milk diet, so he was allowed solid food. His condition then was as follows:

November 29th: Urine passed, 300 c.c.; abdominal measurement—vertical, 14 inches; circumferences, 38½ and 37½ inches. Pulse, 83; temperature, morning 100.5°, evening 102.5° F.

At the end of twelve days (December 10th) his temperature had dropped to normal; urine was 750 c.c. a day; and his abdominal measurements were 13½ inches vertically and 37¾ and 36¾ inches circumferentially.

December 10th: As there were some signs of stomatitis present the powders were discontinued and the patient was put on nitrate of potassium, ʒ i. a day, and iodide of potassium, gr. xv. twice daily in a liquid potion. After eleven days of this treatment without improvement it was noticed that the lower lobe of the left lung was consolidated. Accordingly all medicines were cut off and he was put on a milk diet again with somatose, ʒ iii. a day.

Beginning December 20th with 500 c.c. of milk a day, in two weeks (January 5, 1895) he had run the amount up to 3,000 c.c., and at the same time it was noticed that the amount of urine passed had also increased from 500 to 3,000 c.c. a day; his abdominal measurements were: vertical, 12½ inches; the circumferences, 38 and 37 inches. Accordingly the following mixture was ordered:

℞ Powd. digitalis.. ..... gr. viij.
Make hot infusion ..... ad ℥ iij.
Potassium acetate ..... ʒ ij
Syr. of squill..... ʒ i.
S. Tablespoonful every two hours.

January 23d (seventeen days later) he was taking 2,000 c.c. of milk; urine passed, 1,700 c.c., abdominal measurements still less, viz., vertical, 12 inches. circumferences, 36¾ and 36⅛ inches. As he complained of a little stomach trouble, the milk was now cut down, and beef-tea added to the diet. His other medicines were also stopped except Epsom salts, which was given every morning in ʒ i. dose for a few days, after which the diuretic was again administered.

From January 24th to February 11th the milk was continued in the quantity of 1,500 c.c. a day, the urine passed was 1,500 c.c. (normal), the abdominal measurements went down to 10½ inches (vertical) and 34 inches both circumferences. In view of the fair condition of the patient the milk was left off altogether; but after three days without milk it was found that the amount of urine had decreased, and that the abdominal measurements were increasing It was therefore thought expedient on February 14th to put the patient back on 2,000 c.c. of milk a day, when the urine again increased in amount. The fluid in the chest was now completely absorbed, so that friction sounds and vocal fremitus could be obtained over both lungs. A blister was applied for the sticking pain in the side, and the diuretic mixture discontinued for a few days, but again given when the amount of urine was seen to be decreasing.

Two weeks later (February 28th) the amount of urine was still normal (1,500 c.c. a day). The abdomen was regular in shape, tympanitic, with no sign of fluctuation, and measured vertically 10½ inches and circumferentially 33¾ and 32¾ inches. The subcutaneous abdominal veins could no longer be noticed, and the pain in the chest was gone, although a few friction sounds and râles were evident on auscultation.

The liver could now be mapped out, and it was found that its absolute dulness was limited along the mammary line, above, by the fourth intercostal space; below, by the costal arch. At the parasternal line it reached 2 cm. below the arch. Its limits posteriorly were normal. The spleen was moderately increased in size. One week later (March 6th) pleurisy reappeared on the left side posteriorly, together with slight fever. Salicylate of sodium, gr. xxx. a day, was ordered, diuretics were discontinued.

March 9th: Pleurisy improved, no fever

March 20th: Friction sounds still persisted. Salicylate of sodium was continued. Diuretic potion was again administered, with gr. viii of iodide of potassium, besides ʒ ss. of cod-liver oil with ♏ viiss. of syrupus ferri iodidi twice a day.

From March 1st to March 6th he took 1,000 c.c. of milk a day. Urine passed, 1,000 c.c. Measurements of the abdomen, 10½ inches vertically, 33 and 32½ inches circumferentially.

From March 6th to March 31st 1,000 c.c. of milk a day. Urine passed, 1,250 c.c. Measurements, vertical 10½ inches, both circumferences 32 inches.

March 31st: Weight, one hundred and thirty-eight pounds (his normal weight when in health). There was no fluid in the pleural cavity, friction sounds could be noted all over the left and posterior parts of the chest. Respiratory murmur normal except at the lowest part of the right chest, where it is replaced by fine crepitant râles. The patient has a good appeitte and eats macaroni, meat, eggs, and vegetables in addition to his 1,000 c.c. of milk a day.

April 7th: Tincture of iodine was painted over the chest, where the friction sounds were present.

April 15th: Milk reduced to 500 c.c. a day; urine passed, still 2,000 c.c. a day. Abdominal measurements, 10½ and 32 inches. Friction sounds on left side were less marked. Weight, one hundred and thirty-nine pounds. The daily amount of diuretic mixture was reduced to ℥i.

April 27th: Friction sounds less; ordered iron and arsenic.

May 3d: Friction sounds disappearing. Patient is allowed to go out. A liberal diet was given besides 500 c.c. of milk a day. Diuretic was stopped. Urine, still 1,500 c.c. Abdominal measurements, 10½ and 32 inches.

May 24th: No more friction sounds; few râles on right side of chest low down; weight, one hundred and forty pounds. The patient feels well and strong, and is able to work. I forbade him to work again inside of two years, but he did not heed my advice, and went back to his trade. After working for a number of weeks, he noticed that his hernia, which he could not keep up with a truss, seemed to be growing larger. Examination showed a hydrocele from which about eight ounces of straw-colored fluid was obtained by puncture. This I continued tapping at intervals, thinking that it might gradually disappear. The fluid, however, instead of diminishing in quantity, increased and finally became bloody, until at the end of August about a gallon of bloody fluid was withdrawn from the right side. It was noticed also that the abdominal measurements were increasing. On examining the patient when lying down it was found that the fluid had disappeared from the scrotum. It was thus evident that the fluid in the tunica vaginalis came from the abdominal cavity. This condition had not been noticed during his first sickness, as he was first seen in bed, and was never allowed out of bed until he was well and the ascites had disappeared. In view of the fact that the fluid in the scrotal sac thus pointed to a return of his ascites, puncture of the scrotum was discontinued, and the patient again put upon milk diet (September 21st).

September 21st: Milk, 2,000 c.c.; urine, 2,000 c.c.; abdominal measurements, 34 inches.

October 12th: Milk, 1,500 c.c.; urine, 2,000 c.c.; abdominal measurements, 32⅞ inches.

November 4th: Milk, 1,000 c.c.; urine, 2,000 c.c.; abdominal measurements, 33⅛ inches.

The treatment was then discontinued.

December 27th: Abdominal measurements, 33 inches; weight of body, 137 pounds.

January 12, 1896: Abdominal measurements, 31⅜ inches; weight of body, 135 pounds.

April 27th: Abdominal measurements, 31 inches; weight of body, 137 pounds.

At this time the patient was well and attending to his business. His diet was general, and he drank a little wine with his meals, but no spirits.

The liver was mapped, and its limits of absolute dulness were: In the mammary line—above, at the inferior border of the sixth rib; below, two inches above border of ribs. In the parasternal line—above, at the superior border of the fifth rib; below, one inch below costal arch.

June 30th: Abdominal measurements, 31 inches. The limit of absolute liver dulness was, in the mammary line—above, superior border of the fifth rib; below, one inch above the border of ribs; in the parasternal line—above, at the superior border of the fifth rib; below, one inch below border of ribs. The abdominal veins were normal.

July 18th: The abdominal measurement was 31½ inches.

Remarks on Cirrhosis of the Liver.—Etiology: The cirrhosis, originally described at length by Laennec, and named by him "gin-drinker's liver," by no means depends alone for its causation upon over-indulgence in alcohol. In fact, many other etiological factors have been noted by writers since his time, viz., syphilis,[1] tuberculosis,[2] malignant growth[3] of the organ, malaria,[4] traumatism,[5] diabetes,[6] ptomain poisoning,[7] obstructive valvular diseases of the heart,[8] other cardiac conditions,[9] fright,[10] chronic lead poisoning,[11] and chronic poisoning from sulphuric ether,[12] both experimentally produced, alcohol and malaria together[13] (our case), and possibly a specific, but as yet imperfectly understood infectious disease,[14] as well as an inherited tendency or special dyscrasia,[15] chronic peritonitis,[16] and obstruction of biliary ducts.[17]

Nevertheless, there can be no doubt that alcoholic excess is the most common cause of cirrhosis of the liver,[18] and this is due, it appears to me, not to any special selective action of alcohol upon the liver, but because alcohol is the most common toxic agent to which human beings expose themselves, and because, furthermore, the liver is the first important organ to receive and filter all toxins absorbed from the gastro-intestinal tract.

In the case herewith presented two etiological elements were present: a malaria from which the patient had suffered at one time for ten months, and alcoholism of eighteen years' standing. Only two similar cases in the literature of the past six years has been presented, by Mirinescu (*loc. cit.*) and A. Cardarelli (*loc. cit.*).

Diagnosis.—The large size of the abdomen, the absence of lancinating pains of the peritoneum, the fact that the urine was free from albumin and casts; the presence of the fever only for a few days in the beginning of the disease; the non-existence of organic disease of the heart or œdemas, taken in conjunction with the well-marked abdominal venous circle (caput medusæ), were sufficient to point to an hepatic rather than to a renal, cardiac, peritonitic, or hydræmic origin of the ascites, without excluding a secondary element in the malarial enlargement of the spleen. The relatively large size of the liver before treatment and its marked reduction thereafter tend to confirm the diagnosis of alcoholic hypertrophic cirrhosis of the liver.

Course of the Disease as Influenced by the Treatment.—A careful study of the above-described course of the disease will show the influence exerted by the milk diet upon the flow of urine. Before the steady ingestion of milk the patient was passing a relatively small amount of urine. This amount gradually increased as time went on, till he was excreting by way of the kidney an even larger amount of fluid than he was taking in. During the period throughout which treatment was suspended (May 4th to September 21st), the amount of urine gradually fell, coming up again with the renewed application of the milk diet and remaining permanently high in spite of the lowering of the quantity of milk ingested. This would seem to indicate two things: (1) that the treatment was in the first instance suspended too soon; (2) that the milk diet was the true factor in the cure.

The abdominal measurements are seen to drop proportionately to the rise in the amount of urine. The body weight drops with the rise of the urine curve; this indicates that the loss of weight in this period of time is due to the disappearance of the ascitic fluid. The highest point of it corresponds with the premature suspension of the milk diet (May 24th) and is permanently kept to the average weight of the patient when in health after the final suspension of the treatment. To-day, about five years since the treatment was stopped, the patient is perfectly well, having a good appetite, digesting the strongest kind of food, and attending to the heaviest labor of his trade. He has,

however, entirely abandoned the use of whiskey, and is abstemious in regard to other alcoholic drinks.

Curability of Cirrhosis of the Liver.—Quite a number of cases resulting in cure have been recorded in the literature. Fritz[19] reports an apparently hopeless case quickly cured by daily doses of strychnine, 1 cgm., together with 4 gm. of potassium iodide, and though he does not pretend to explain the reason for the cure, he says that physicians should never give up hope in the treatment of cirrhosis.

Rendue[20] reports cure in a case after fourteen paracenteses, during which two hundred and eighty pints of fluid were withdrawn.

A. L. Romain,[21] a case of cure by milk diet and iodide of potassium.

Croisier,[22] five cases cured by repeated paracenteses.

Soucerotte[23] reports a cure after four months' treatment and quotes cures at the hands of others (Féreol, Descurt et Vulpian, and Richard) as the result of treatment ranging in length from two months to two years. He cites a patient of his father who lived thirty years after being cured.

Senator,[24] a case of cure in four months.

Wirsing,[25] besides reporting a case of his own, collects many others from the literature.

D. De Buch et L. De Moor,[26] Beerens,[27] B. C. Sen[28] et H. Delagenière,[29] among the more recent authors, report cases of cirrhosis of the liver resulting in cure.

Budd,[30] Cornil,[31] Rendue,[32] Frerichs,[33] Cirelli,[34] and others of the older writers had no faith in the curability of cirrhosis of the liver, believing that, when ascites has once developed, nothing can be done beyond amelioration of the symptoms.

As will appear from the dates in the bibliography, it is the more recent writers who have advanced a more hopeful view and have brought forward cases to support it. It not infrequently happens that experience and theory fail to harmonize; and in view of the clinical facts and of the newer cytology we must conclude that the reasoning of the older writers was based upon an imperfect conception of the effect of toxins. In fact, the very existence of such products was hardly suspected.

In the present case, after about five years during which treatment was stopped, the patient displays no evidence of his former trouble. An enlargement of the spleen existed, but that was undoubtedly of malarial origin, since only the atrophic form of cirrhosis can produce splenic hypertrophy.

A most interesting fact, and one which should have considerable value as showing the changes in volume that the liver may undergo during the course of a cirrhosis, will appear upon examining the measurements taken at different times during the course of the disease.

The vertical diameter reached its maximum on February 28, 1895, its minimum on April 27, 1896, and with a marked improvement of the symptoms, on June 30, 1896, had returned to a point between these two extremes.

Wide variations in the size of the liver during the course of a cirrhosis have been noted by Duncan,[35] Senator,[36] H. W. Webber,[37] Debove,[38] A. A. Eshner,[39] and a unique case was reported by Markvall,[40] in which the autopsy showed in some points of the liver atrophic tissue, in other points of the same hypertrophic tissue in the form of round masses of newly built hepatic parenchyma, as was proved by the microscopical examination. Hanot and Gilbert[41] also report a case of atrophic cirrhosis of the liver in which, at the autopsy, besides an atrophic lesion a process of regeneration of hepatic tissue was found. Remarks on this process of regeneration were also in the last decade published by D. Nasse,[42] J. B. Gibbon,[43] V. Hanot.[44]

It is not surprising, therefore, that a case which ended in recovery should present the changes in size that were noted. The final increase in volume parallel with the improvement of the symptoms would seem to point to a regenerative process in the organ, and we may even assume that this regeneration was the *sine qua non* of recovery. Nor have we any reason to believe that such a process is confined to the liver, but rather that this same regeneration of damaged cells takes place during recovery of any organ from disease.

The Infectious Nature of Cirrhosis.—The following facts tend to show that certain forms of cirrhosis of the liver may be due to a special infection:

1. Cirrhosis is not peculiar to the liver, but can affect any organ.

2. Many cases have followed a very rapid course.[45]

3. In many cases the state of the blood is much depraved, as evidenced by hemorrhage[46] (which was present also in this case in form of bloody ascitic serum), although said hemorrhage can be produced even by varicose veins[47] complicating a dyscrasic condition of the blood.

4. Certain known infectious diseases[48] cause cirrhosis.

5. Microparasites have been found in cirrhotic livers.[49]

6. Coma[50] and delirium[51] have been noticed during the course of certain forms of cirrhosis.

The subject is too extensive to be more than touched upon in this place, but possesses rich material for discussion.

Treatment.—As to the treatment of this case, the therapy consisted of milk, iodide of potassium, and diuretics. The milk was administered from start to finish; the iodide of potassium and the diuretics, though not used till late, seemed to contribute in considerable degree to the cure. The milk sustained the patient without throwing work upon the liver as would have been the case if the patient had been allowed fatty or starchy food, while at the same time its diuretic properties were of exceeding benefit.

The iodide of potassium probably acted as a solvent upon the hypertrophic connective tissue, and probably as an antiseptic, while the diuretics were selected from those that would not only assist in eliminating the waste from the body, but so strengthen the heart and blood-vessels as to restore the hydraulic equilibrium.

General Remarks on Other Treatment.—Very many therapeutic measures have been adopted in the treatment of alcoholic cirrhosis of the liver: Copaiba either alone[52] or with milk and iodide of potassium[53] with good results; calomel gr. iii. daily with mouth wash of chlorate of potash;[54] milk, Vichy water, potassium iodide, and nux vomica,[55] without result. Paracentesis, when repeated often enough, sometimes completely relieves the ascites.[56] Lecanu performed it upon a single patient eight hundred and eighty-six times during fifteen years.

Milk, diuretics, and potassium iodide,[57] with resulting cure. Milk and puncture,[58] case resulting in cure. Milk and potassium iodide with resulting cure by Lancereaux[59] and by Semmola,[60] who says that milk, if used long enough in large doses, will cure cirrhosis. Milk and calomel,[61] with result in death due to an infectious condition of the blood.

Strychnine and potassium iodide,[62] 1 cgm. of the first and 1 gm. of the second daily, caused rapid recovery through diuresis after Vichy water, potassium iodide, nux vomica, and puncture had been employed without result.

Laparotomy[63] in a cirrhotic for diagnostic purpose resulted in cure.

Drainage,[64] invariably resulting in death sooner or later.

Packing of the abdominal cavity,[65] constantly resulting in death.

Milk and gin,[66] death following.

Calomel and puncture,[67] with no good result.

More recent authors (Villemin and Chresteu de Monpellier, quoted by Dujardin-Beaumetz, Ferreira, De Renzi, and Semmola) registered cases of patients cured of cirrhosis of the liver, having used diuretics, drastics, iodine preparations, and above all milk.

Bearens (*loc. cit.*) reports a case of a cure with repeated paracenteses and application of a caustic (Vienna paste) in the hepatic region. Klemperer (*loc. cit.*) cured a patient with milk and urea as diuretic. Verstraeten (*loc. cit.*) cured one with Vienna paste and eleven paracenteses, by which he drew 9½ litres of fluid. Of these various remedies the greatest number of favorable results seems to have been obtained by the plentiful use of milk combined with potassium iodide or rarely with tapping, this last part of the treatment being purely symptomatic, and though useful at times, extremely dangerous if often repeated. For, besides the danger of ill effect from traumatism of the peritoneum and of possible infection, an amount of albumin is drawn off which takes a long time for the blood to recover, and which a patient in a low state can ill afford to lose. Milk therefore should be our mainstay in the treatment of this disease, and though it takes a long time for it to perfect a cure, in a disease of such importance we can afford to make haste slowly.

Summary.—1. This was a true case of hypertrophic cirrhosis of the liver due to alcoholism.

2. The patient was entirely cured with milk, potassium iodide, and diuretics.

3. The cure probably depended upon a regeneration of the damaged cells of the organ.

4. For the complication that arose, *i.e.*, sero-fibrinous double pleurisy with partial consolidation of the left lobe, only local treatment was used in addition to the regular treatment for cirrhosis, and yet these conditions were entirely cured.

A study of this case, together with the cases reported in the bibliography below, will give prominence to three facts:

1. Alcoholism is by no means the only cause of cirrhosis of the liver.

2. Alcoholic cirrhosis of the liver is curable; the hypertrophic form more often, but the atrophic form also.

3. Cirrhosis very often shows symptoms characteristic of an infectious disease.

THE CO-OPERATION OF THE MEDICAL PROFESSION OF THE UNITED STATES WITH THE NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS, IN ESTABLISHING INTERSTATE RECIPROCITY FOR THE LICENSE TO PRACTISE MEDICINE.[1]

By EMIL AMBERG, M.D.,

DETROIT, MICH.

It was with a feeling of embarrassment that I accepted the kind invitation to read a paper before this confederation. There certainly cannot be anything new that I may be able to present; however, since the committee of the Wayne County Medical Society, of Detroit, has become a kind of a centre for the exchange of opinions along the line of interstate reciprocity for the license to practise medicine, it may be of interest to hear some of the ideas which were furnished to this committee and stimulated the movement.

Before entering into the subject proper, I take great pleasure in expressing my thanks—and I am sure our committee and our society are in accord with me—to all the medical boards and medical State officials in the United States. In fact, the movement is partly based on the willingness of these authorities and on the interest they take in the matter. The question might be raised why the whole movement might not better be left to the National Confederation instead of enlisting the whole medical profession in the same. We can answer that the aim of the National Confederation of State Medical Examining and Licensing Boards, their efforts and their works are, no doubt, highly appreciated by the medical profession. Two points, however, make it desirable that the whole medical profession stand shoulder to shoulder with the boards: First, the feeling of equal citizenship, and, second, the fact that the changes toward an improvement have to go through the legislative bodies.

Concerning the first point, we must consider the peculiarity of our country and our form of government. As to the second point we know that the laws necessary for our purpose must be enacted voluntarily. If it can be expected from every citizen that he understands why he expresses his will on the proper occasion, it must with right be taken for granted that the learned members of the medical profession know why they will depart from the old rules and why they will assist the members of the various boards in their efforts toward an improvement.

There exists no doubt that the advancement of medical science in any country demands a progress in medical education, and, if it were only for this reason, a standstill cannot be tolerated. But let us consider whether we must not improve, if it were only for the purpose of reaching that point which would place the medical profession in the United States on an equal footing with those in the most advanced countries. Physicians are the products of the medical schools; therefore we may speak at the same time of the medical schools. Permit me to quote from quite a number of authors, because I think in repeating their remarks we will have a good idea of the opinion of the medical profession on the subject.

Mr. James Russell Parsons, Jr., in his monograph on education in the United States, gives the number of medical colleges in the year 1899 as one hundred and fifty-six, excluding post-graduate schools, with twenty-four thousand one hundred and nineteen students. The Medical Record (March 17, 1900), quoting Mr. Parsons, says: "A foreigner, reading this statement, and unacquainted with the facts of the case, would come to the conclusion that the medical education in this country was in a particularly healthy condition. If, however, he were of a curious disposition and would dive more deeply into the matter, his opinion would assuredly undergo a radical change."

It is evident that the standards of one hundred and fifty-six medical schools vary a good deal. Their sufficiency at present must be tested by the boards. The *Philadelphia Medical Journal* says well (in the issue of April 14, 1900): "Medical examining boards have a distinct power and well-defined duties in regard to these matters; they can refuse to recognize the diplomas of colleges that give insufficient instruction. Every examining board should have an 'inspection that inspects' every school whose diplomas they agree to recognize."

I, for my part, go even further; I do not believe in private medical schools at all. It is the duty of the State to provide for the education of physicians through first-class medical institutions. The State can do this through boards which are independent of party politics. Parsons, in speaking of the meagre endowment of medical schools corresponding to those made to other educational institutions, says: "Fortunately, the closing year of this century seems to indicate a change in the attitude of philanthropists toward medical schools." In my mind there ought not to be any necessity for the medical schools, institutions of vital importance for the people, to be dependent upon alms. Dr. Roosa, president of the New York Post-Graduate School, is reported to have said: "I hold that the State ought to furnish sufficient funds for the adequate and thorough instruction of all the

[1] Read before the National Confederation of State Medical Examining and Licensing Boards, June 4, 1900, at Atlantic City, N. J.

pupils in every medical institution already legally organized, and for such others as the increase of population may cause to be established under the regulation of the State." Contrary to Dr. Roosa, I hold that the State has not the right to support private corporations at the expense of all citizens. If the different political divisions would take charge of the medical schools there would be a decrease in the number and an improvement in the quality. I naturally admit that we have some good private medical schools; this, however, does not change the aspect and does not excuse a system which has detrimental effects upon the medical profession and upon the public. Conditions at present equal a hazard game. It is not necessary for me to indulge at length on this subject before this body. I may be permitted to quote only the remarks made by the *Boston Medical and Surgical Journal* (October 12, 1899), which, in speaking of "uniformity requirements," says: "We need, first, to reform our medical education, and, when that is satisfactorily done, uniformity of standard will be attained without recourse to legislation. We are, therefore, strongly of the opinion that the real question at issue is to regulate the character and attainments of the men who are about to study medicine, rather than to attempt to legislate into positions of respect men who, from the beginning, were unfitted for the duties and responsibilities of their profession."

In establishing reciprocity, the question of preliminary and medical education is of paramount importance, and there cannot be an independent member of the medical profession who would not admit that uniform training is the foundation of uniform rights in all States and Territories. We fully agree with Dr. William Warren Potter when he says under the heading, "Equality of Standards a Basis for Reciprocity":[1] "The only equitable basis upon which reciprocity can be established, that appears both feasible and practicable, is that of equality of standards for admission to the study and practice of medicine. This implies an equalization of the preliminary requirements of medical students and a uniformity of applying the tests, a uniform period of collegiate training, including uniformity of methods of teaching, and, finally an absolute similarity in the method of conducting State examinations and granting licenses." Dr. Potter's ideas are known to you, no doubt. I wish they were known to the whole medical profession in the United States.

I might mention here, that it is distinctly understood by all parties that it is not expected that any board lowers the standard of requirements. Also some other points should be considered. I may be permitted to quote part of a letter which I received from the Maryland State Board. It reads: "The board is not, at present, disposed to enter into reciprocal relations with other States without receiving some power by exercise of which an undesirable physician could be kept out of Maryland; a man might be all right when he received your license, and subsequently become very bad." This letter I regard as very important. The board acknowledges the necessity of exercising some kind of a control of the moral character of a physician, if I understand the letter right. There does not exist any doubt that such a control is very desirable, even necessary. In this respect the answer is very suggestive to all boards and legislators. On the other hand, I cannot understand that this question touches directly upon the interstate reciprocity agreement. If a man is undesirable in one State he certainly is undesirable in all States—not less so in his own State. We have here to deal with two questions which are practically independent one of another, and the disapproval of existing conditions concerning one point does not excuse the refusal to co-operate in another.

There is also a letter from another board in my hand, the contents of which will be of great interest. It reads, in part: "We, as a board, have made it a rule to issue no license to practitioners, except in compliance with the requirements of our own laws. Owing to the fact that some States which have good medical laws seem to have boards that are very lax in enforcing their requirements, we have deemed this course not only advisable but absolutely necessary in regulating this matter in our own State. So long as the authority for authorizing a license is invested in the members of the board to the degree that it is in many of the States, we do not feel that we can consistently enter into any interstate reciprocity, even if we had the legal power to do so. This board has just received a personal recommendation from the president of the —— State board of medical examiners, in behalf of a man whose sole claim for recognition was a diploma issued by one of the most disreputable "mills" in the country. As long as State boards are so entirely indifferent in performing their duties as the one above mentioned (the applicant is a registered practitioner in ——), we are distinctly opposed to reciprocity with such people. It is needless to say that the applicant was refused a certificate."

My remarks made before apply also to this letter. Nobody expects that any board recognize diplomas of diploma mills. The boards can agree upon a few colleges the diplomas of which they will recognize, without including the others. It should not be difficult to select some medical schools which require a high preliminary education and which guarantee a thorough medical training.

Although we recognize the commendable work done by the Association of the American Medical Colleges, the boards, in my mind, cannot recognize all the colleges of the same. The association may be a very necessary institution, but as far as the profession in general is concerned, and also the public and the boards which form the connective link between the public and the profession, there does not exist a close connection between them.

As I expressed it on another occasion, in establishing interstate reciprocity the process of evolution has to be followed, in order to have a sound development. There is no doubt in my mind that by steady work and perseverance the desired results will be attained in the course of time. The question, however, arises, whether anything can be done immediately toward the end in view. It appears to me that we may answer this question in the affirmative. In a communication to the *Medical Examiner*, of New York, I took occasion to state my view concerning the temporary division of States into six groups, taking as a basis the preliminary education, the medical education proper, and the final State examination. This view was commented upon by the *New York Medical Journal* of January 20, 1900. Parsons, in his work,[1] says: "The present needless multiplication of standards, however, is most unfortunate. Instead of a separate standard for each political division, two, or at most three, standards should answer for all."

It assuredly would be preferable to have two or three groups instead of six, but I doubt whether such an advanced step can be taken at present. I admit that six groups are a little numerous, but six are preferable to fifty-one or more groups. There is no doubt that the formation of groups would not only benefit a great part of the medical profession immediately, but also would help toward the final aim. No better proof

[1] "Reciprocity in Medical Licensure; a Plea for Interstate Indorsement." The Bulletin of the American Academy of Medicine, vol. iii., No. 1.

[1] *Loc. cit.*, p. 45.

can be brought forward in favor of this view than the welcome and timely action of the boards of the New England States. There was a meeting held at the State House at Boston, on February 1, 1900, which, in my mind, is of fundamental importance in the history of medicine in the United States. Not too much praise can be given to the originator of the meeting and to those who participated in the same. We read in the report that "the object of the meeting was presented by the president, who stated that it was generally conceded that reciprocity would be desirable, and suggested the need of discovering the best means of guiding the legislation in order to unify the laws governing medical practice in the different States. Efforts should be made to secure like standards, uniform severity of examinations and markings, like duration of examinations, like subjects, the same fees, the same rules as to conditions, etc., and the same frequency of meetings in the various States."[1] The medical profession, I think, is expecting to see other groups formed. I know that the great majority of the boards have not the right to enter reciprocity until the laws of the respective States and Territories have been changed.

Experience teaches us that it requires great efforts on the part of the medical profession to educate the law-makers and the public, in order to convince them of the usefulness and necessity of changes. Unfortunately, it seems that, for some reason or other, the law-makers are sometimes more influenced by the adversaries of the general good than by the friends of the same. We fully agree with Dr. William W. Potter when he bitterly complains of this fact.

Also another step forward can be made without much delay and trouble. The secretary of the American Academy of Medicine, Dr. McIntire, offers the following commendable suggestion in the Bulletin of the American Academy of Medicine (December, 1899): "To hasten the desired result it would be well if the various licensing bodies would take cognizance of the fact that the legal minimum requirements are more severe in some States than in others, even though the board may, at its own volition, keep the standard higher than the minimum requirements specified by law, and where any State has minimum requirements less exacting than those of another State, if it would accept the licenses from another State having the higher legal requirements without reciprocity it would work no harm to its own physicians and, at the same time, show a good will that could not but help, in the course of time, to aid in the general exchange of licenses." I fully agree with the doctor, and I think it is an injustice to make reciprocity dependent upon the condition that the certificates of the weaker States are accepted by the stronger States. It seems to me that the boards should not place a tariff on knowledge and skill. If the weaker divisions are unable to furnish a sufficiently good education, the boards should welcome the licentiates from the stronger divisions. This will work as a stimulus to the weaker divisions, and is justifiable from a moral and humane point of view.

Concerning the relation of the medical profession in general to the National Confederation, in the efforts toward interstate reciprocity, we readily see that their work is interwoven. I may be permitted to call attention to some other points in connection herewith. We know that it is the aim and the object of the National Confederation of the State Medical Examining and Licensing Boards to establish the standard of medical education in all its details. We know also of the good work the Confederation is doing, and are already convinced that its efforts, in general, are in the right direction. Therefore, it appears to me that the medical profession can heartily indorse the work of the Confederation and pledge their support in pursuing the same.

The co-operation of the medical profession at large is shown, and can still more be shown, in the following ways which are familiar to you. In the first place, it is advisable that the medical profession constantly keep in touch with the work and with the intentions of the Confederation. In this way the profession will be aware of the progress of the work. I may suggest, in this place, that a journal, perhaps a bi monthly journal, be edited by the Confederation in co-operation with the profession at large. It might treat all subjects in connection with interstate reciprocity and higher medical education The profession could thus become more thoroughly acquainted with all the details of the question.

Furthermore, the medical profession can materially assist the boards in helping to establish and to change the laws in the different political divisions This, I think, can be regarded as the most important assistance on the part of the profession It appears to me that in this time of unsettled affairs a public spirited citizen, even if he be a physician, has the duty to do all in his power to instruct and to educate the public concerning these subjects Can we expect otherwise to accomplish anything, and who else could do this work if the medical profession will not do it? I cannot believe that law-makers have not the intention to work for the good of the people If they sometimes are more inclined to follow the advice of the enemies of the welfare of the community, this fact certainly can be explained, in most cases if not in all, by the lack of understanding I think that the medical profession itself is to blame for this to a great extent. The medical profession should furnish to the law makers the necessary knowledge We have a powerful profession in the United States, and if all members, or the great majority of the same, would be a little more aware of their duties as citizens and use their influence, uniting their efforts toward an improvement, there would be a speedy change. It has recently been seen in Michigan what the medical profession can do. There is no doubt that the physicians under proper guidance, have a great influence upon public opinion, and nothing, it seems to me, has greater weight upon the law-makers than the latter. Individually and collectively the medical profession should stand by the Confederation in this respect.

The *Journal of the American Medical Association* (May 12, 1900), speaking of the Ohio medical law, says (on page 1205): "The passage of this amended law is full of fruition of the dreams of many years of the leading Ohio members of the profession, and it required the most assiduous and most self sacrificing labor on the part of the legislative committee of the State Medical Society, assisted by committees of the local societies. The result, however, clearly demonstrates that when the medical profession shows itself to be determined in its requests to the politicians it can overcome all opposition."

Also another important factor should be considered. We know that the public opinion is largely influenced by the daily press. I think it is commendable to interest the daily press and to furnish the individual editors with material. They will draw the proper conclusions themselves. It affords me great satisfaction to state that the people of Michigan are greatly indebted to the daily press in our State for their new law. I am especially familiar with the assistance of the press in Detroit. With great interest the press watched the work of the better part of the profession. After becoming convinced of the necessity of changes, it worked for them with unceasing efforts, and could see its work crowned with success. Independent of

[1] Rhode Island Monthly Bulletin, February, 1900, p. 45.

one another in their ways, combined, however, by the general principles of humanity, the press and the profession in Michigan have worked together for the benefit of all, and I sincerely hope that both will continue to do so in the future. The greater part of the work is still before us (I may mention that at that time there did not exist a State board in Michigan; it has been created since then by united efforts). Should the lay press in all sections of the United States follow the example set by the papers in Detroit, conditions all over the country would improve more quickly.

The co-operation of the medical profession with the boards, to their mutual benefit, can also be shown in a way which suggests itself to me through a communication by Dr. John S. Lewis, president of the Dubuque Medical Society. Dr. Lewis says, partly quoting from another source:

"State boards, from the manner of their appointments, are transient not only as to their constitution but as to their character. They are often creatures of a political system, with which barter and sale, and compromises, and pledges have had to do, and they owe debts; the result is that some of them will be efficient and some will not and that the element of stability in their judgments will be lacking. State pride of a very poor quality will influence a certain order of minds to favor the product of their own State institutions, and it is not inconceivable that even worse motives may actuate them. Besides this, who is going to judge of the standing of the various State boards and assign them to their proper places in the six classes you propose?"

I may answer that we should consider that we are obliged to start the work with our present material. The State boards will improve, no doubt, in the same degree as the profession in general. Both will co-operate with each other for their mutual improvement. Concerning the six groups and the assigning of the various boards to their places I should like to say that the formation of groups should not be based on the quality of the boards so much as on the sufficiency of the laws. There exists little doubt in my mind that the members of the various groups will exercise a sharp control among themselves.

There is still another way in which the individual physician can help to purify the medical profession and at the same time help the cause under consideration; I am thinking of the duty of a physician to withdraw his support from advertising medical journals. It has been said we have two hundred and fifty medical journals in the United States. A great many of these journals are certainly not only superfluous but they are absolutely detrimental to a higher medical education and to the profession. Furthermore, the medical profession can work in the behalf of interstate reciprocity and higher medical education by constantly keeping in mind that medical schools, with greater benefit to all, should be public institutions, as I mentioned before. In connection herewith permit me to add part of an editorial of the *Philadelphia Medical Journal* of May 5, 1900, which comments upon the ideas of Dr. Bowditch, of Boston, expressed in his paper, "The Medical School of the Future." The *Journal* says, among other things:

"These suggestions are of the greatest importance for the future of American medicine; the introduction of the university idea, the laboratory method of instruction, the practical examination to test the student's real fitness for practice, and even the Harvard arrangement of courses in due sequence, are all, apparently, past the experimental stage. Every member of the profession should use his influence to support such schools as are working for these ideals, and the entire profession, through its societies, should organize to support such schools and to use the profession's best influence to crush the inefficient diploma mills which exist in such numbers in almost all parts of our country. Aside from the more ideal motive of striving for that which is best in medical progress, there is the very practical motive which must appeal to every practitioner, that the profession is daily becoming more and more crowded with inefficient men. According to the *Bulletin on Professional Education*, of the University of New York, there is already one doctor to about six hundred inhabitants in most sections of the country, and if this increase continues an honorable living in the medical profession will be almost impossible."

In following out this principle the co-operation of the medical profession with the Confederation will not only serve the purpose mentioned, but will also more or less improve the conditions of which we constantly read, viz., the overcrowding of the medical profession, unethical advertising, the catering to ignorant and incompetent pretenders, the question of the different pathies, the leaning toward Christian scientists and toward patent medicines, the question of specialism, the position of medical experts, the dark sides of medical journalism which I mentioned before, of lodge practice, the abuse of free dispensaries on the part of the profession and the public, the social standing of the medical profession in general, etc. At present we are moving in a "circulus vitiosus." United efforts of the Confederation and of the medical profession should create, instead of it, a "circulus nobilis."

That a greater part of the medical profession all over the United States understands its position is clearly shown by the great interest which the medical press, medical societies, and individual physicians take in the work aiming at interstate reciprocity. Also the laity is beginning to take interest in the question. In order to further the movement I venture to suggest that an interstate reciprocity committee be appointed by the National Confederation of State Medical Examining and Licensing Boards, which may keep in touch with all other interstate reciprocity committees which may be appointed by other bodies, and also that this or a separate committee may be authorized to publish an *Interstate Reciprocity Journal* perhaps in connection with the medical profession at large—if it sees fit to do so.

In conclusion, permit me to say that the movement is important also for another reason. It seems to me that the next century will witness the greatest progress in the history of mankind in regard to hygienic measures. It, perhaps, will be called the "hygienic century." A hundred years hence the then living generation will be entitled to name it so, if only the facts discovered in this century will have more generally been used for the advancement and happiness of the human race. We have reason to believe that this will be done. With unusual activity all civilized nations are taking part in the fight against the ravages of diseases, *e.g.*, tuberculosis. It is the duty of the National Confederation of State Medical Examining and Licensing Boards to provide for a well-prepared medical profession which will be leading in the march of progress, and it is the desire of the medical profession of to-day to do all in their power to help the Confederation to this end. May every single member of the profession contribute his share.

Even a superficial study of the question will convince every citizen of the United States, be he a physician or not, that the establishment of interstate reciprocity for the license to practise medicine is in the interest of all.

Woman's Medical Rights in Austria.—Women are now empowered to practise medicine and pharmacy in Austria on the same conditions as men.

TREATMENT OF FRACTURED PATELLÆ.

By WILLIAM B. TRIMBLE, M.D.,

INSTRUCTOR IN CLINICAL SURGERY (NEW YORK UNIVERSITY), UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

Realizing fully that this subject has been very widely discussed and is somewhat time-worn, it is my desire to give a short résumé of the different ideas of treatment in cases of fractured patellæ, and to speak briefly in advocacy of the wire-suture method, reporting three cases operated on by me in this manner.

The causes of fractured patellæ, like those of fractures elsewhere, are direct violence and muscular action. Direct violence usually produces comminuted fracture, and past writings upon this subject show quite conclusively that bony union in this variety of cases is a frequent result; one accountable reason for this is that the comminution and multiplicity of fragments produce a larger extent of raw surface; hence more callus is formed. However, we must guard against ankylosis, which is often a serious source of trouble in these cases. All fractures of the patellæ from muscular action are transverse, and as this variety is the one most frequently encountered by the surgeon, this article is confined more or less to a consideration of cases of simple transverse fracture of the patellæ.

To get bony union is the aim of all our efforts, and to do this the fragments are to be brought together and held (with the accent on the held) in direct apposition. Surgeons of the present day do not expect union from non-operative treatment, and, although it may happen in rare instances, it is a surgical curiosity.

From a palliative standpoint, numerous splints and appliances have been devised; all of which have the same end in view, viz., direct apposition, bony union, etc.

A few of the best of these methods will here be enumerated. A time-honored, popular, and excellent method is that with adhesive or rubber plaster strips. A posterior wooden splint, padded, should be applied, extending from the middle of the thigh to the tendo Achillis; a compress is placed just above the upper fragment; and over this, in an oblique direction, should be placed a strip of adhesive plaster about one or one and a half inches wide, which is carried downward encircling the leg and splint below the lower fragment; the lower fragment should be treated in the same manner, and the strip of plaster carried upward and attached to the splint and thigh above the upper fragment; a roller bandage, carried from the instep to the middle of the thigh, completes the dressing.[1]

Agnew's splint may also be employed; it consists of a posterior wooden splint with pegs, to which the ends of the rubber plaster are fastened. It is a modification of the foregoing, and the end in view is identical. Other splints, such as Manning's, Thomas', etc., have been put forward by their originators, and have their followers, but time and space prevent a full description of them; however, as said before, they like the others have the same objective point.

All splints should be worn from six to eight weeks, during which time the foot is kept elevated to relax the quadriceps as much as possible; after this, a plaster-of-Paris dressing, split down the centre to facilitate removal and passive motion, is worn, the length of time being left to the attending surgeon in each individual case.

We now come to what may be called the semi-operative treatment, and under this head will be placed Malgaigne's hooks, the long steel pins of Mayo Robson, and the circumpatellar subcutaneous suture of Mr. Barker.

Malgaigne's hooks have been justly called instruments of torture, owing to the severe pain and excessive irritability that they produce, and oftentimes the complaints of the patient will be so forcible that it will be found inexpedient to use them; however, it must be said in their favor that they come nearer to accomplishing the purpose sought than most appliances. In treating a fractured knee-cap by this method, thorough antisepsis should be resorted to, and the punctures, four in number, are first made down to the bone with a tenotome; the hooks are then inserted, first in the lower and then in the upper fragment, and the parts are brought together by turning the approximating screw.

The treatment by long steel pins is usually credited to Mayo Robson, of England; they have been used to some extent and have undoubtedly some favorable results. The writer first saw this method demonstrated by Dr. James E. Kelly, of this city. It consists in passing two steel pins each about six inches long close to the fragments, one through the tendon of the quadriceps and the other through the ligamentum patellæ; the ends are then wrapped in a figure-8 manner with heavy silk or silver wire to draw the fragments together. An addition to the technique of the above plan was to take the third pin, plunge it in one side of the joint, between the fragments, but not allowing it to emerge through the skin of the opposite side, and an upward and backward sawing motion was gone through with, as the pin was withdrawn; it was suggested in the hope that any interposed tissue might be lifted from between the pieces. The idea is somewhat far-fetched and not practical.

The best of the semi-operative procedures to be discussed here is the circumpatellar subcutaneous suture of Mr. Barker; the technique is somewhat similar to the subcutaneous operation for varicocele, viz., the long curved needle is passed through the ligamentum patellæ, close to the lower border of the lower fragment, under the patellæ, and brought out through the tendon of the quadriceps and skin, and then threaded with heavy silk or silver wire and withdrawn; the needle is again inserted through the original puncture, this time going over the broken bone, and threaded with the other end of the suture; the ends are then tied tightly into several knots. The originator lays claim to many good results, and the method is steadily growing in favor in England.

Very recently, that is, within the past year, several cases of fractured patellæ treated by the so-called massage treatment were presented at the Academy of Medicine; it developed during the discussion that the treatment consisted in putting up the injury with the posterior splint and adhesive plaster strips, it being daily taken down, and, while the surgeon strongly held the fragments, a masseur manipulated the injured limb, beginning at the hip and working down to the knee.

The writer does not wish to criticise massage adversely in any way, as it undoubtedly has its advantages, viz., relieving pain, increasing the circulation, removing exudate, and acting as a form of passive motion, etc.; but we are forced to agree with one of the gentlemen in the discussion, that the term "massage treatment" is somewhat of a misnomer, as the cases referred to had been previously treated by the surgical appliances used by most medical men.

Numerous ideas and plans of treatment arise from time to time, and efforts sometimes crowned with some success have been made to supply the profession with a contrivance which, while keeping up the proper amount of extension, would not confine the patient to bed. A most unique device of this kind was suggested

[1] The case of Harriet C—— was treated by the author in this manner. She was seen almost immediately after injury, and as the quadriceps had not contracted there was practically no separation of the fragments. A beautiful result was obtained.

by Dr. Joseph D. Bryant; its description being a little too long to incorporate in this article, the reader is referred to the MEDICAL RECORD of April 4, 1896. As said above, various kinds of treatment occasionally present themselves, and although some are unique in design, possessing perhaps some new advantage, the main objectionable features still exist.

We come now to the operation proper. Our text-books tell us that, although this operation seems to be a brilliant mode of treatment, it is sometimes associated with loss of limb, and has been known in some instances to endanger life; therefore they have drawn the conclusion that the nature of the lesion does not warrant such heroic measures. This opinion was maintained by some of our older writers, and is still held by a number of the surgeons of the present day, consequently the operation has been slightly overshadowed, though it has by no means fallen into disrepute. In the last few years, this method has been strongly urged by Dr. Charles Phelps of this city, in whose practice I have had occasion to see many happy results. All forms of treatment admit of cavilling and argument, but after a careful review of the whole subject both practically and theoretically, the radical operation seems to have the fewest objections. They are the same as those against operation on any part of the human body, viz., fear of shock, anæsthesia, and suppuration. The physical shock accompanying this procedure is no greater and no more to be feared than in operations on other parts of the body, and the only danger to life and limb appears to lie in the fact that suppuration may take place, pyæmia result, etc. Happily the cases resulting in this manner are very rare, and strict adherence to the rules of aseptic and antiseptic surgery will prevent any such unfortunate occurrence.

Objections to the non-operative plan are exceedingly numerous, some of which cannot be remedied unless the treatment be changed and finally result in operation.

When the patella is broken by muscular action, which is usually the case, its aponeurotic covering and synovial membrane are in the great majority of cases torn below the level of the line of fracture; hence we have folds of ligamentous and aponeurotic tissue interposed between the fragments, which will in all cases prevent osseous union.

In order to control the quadriceps extensor muscle, great pressure must necessarily be made over the upper fragment; this pressure often threatens to stop the circulation, which is a serious obstacle to a good result, and in one instance, which comes to the author's mind at this time, the tissue over the whole front aspect of the patella sloughed away. Again, cases have come under the writer's observation, in which the pain, œdema, irritation producing traumatic dermatitis, and other disagreeable symptoms caused by mechanical contrivances were so unbearable that they would not be tolerated by the patient. The above statements are corroborated by Manning, of London, who has found, after numerous dissections of the arteries which supply the patella, that the arch by which the upper fragment is supplied is situated in the exact place where the greatest amount of pressure is applied, and in a great majority of cases the superior and inferior articular arteries arise from a common trunk, thereby cutting off the blood supply from both fragments, he has also found that in a limb injected after being "put up" for this fracture, all the arteries are filled except those supplying the patella.

The fibrous or ligamentous union gained by the various non-operative measures is claimed by some to be equally as good to restore function in the injured joint as bony union, and although it is very firm and close in some cases, it will invariably stretch to some degree, and not a few cases have been known to allow of separation to the amount of two or three inches; this will undoubtedly weaken the joint and not infrequently deprive the patient of all power of extension in the limb, and leave him a cripple for life. Stimson has justly said "that the test is found in time and use," and it is quite common to see a gap, which is very slight at the time treatment ends, increase to the width of half an inch or more in the course of a few months. Ankylosis is one most formidable enemy in treating these cases, and although it sometimes occurs, especially following the refracture, if the limb be watched and carefully attended, viz., lateral motion and flexion begun very early, such a condition of affairs will be averted, and we can in most cases give a favorable prognosis.

The time of operation seems also to be a question of dispute, and it has been stated by several surgeons that the time proper is within twenty-four hours after the accident. This is good advice to follow, provided all the acute inflammatory symptoms have subsided: if not, it certainly seems to be better surgery to wait until they have, as experience very forcibly teaches that cutting into œdematous and contused tissue frequently causes sloughing, a condition which we most assuredly wish to avert.

A good course to pursue is to treat the case palliatively by pressure bandages and cold applications, until all swelling and inflammatory signs have ceased.

The operation undertaken by the writer in the cases reported is as follows:

The knee is put in a soap poultice twenty-four hours prior to operation; on the morning of operation, it is thoroughly scrubbed with water and tr. viridi saponis, then washed with solution of bichloride of mercury 1:2,000, this is followed successively by turpentine, alcohol, ether, and lastly bichloride again The incision is made transversely between the fragments, opening the joint; all blood clot is washed away by continuous irrigation (bichloride of mercury 1:2,000), and the ragged aponeurotic fringe is lifted from between the broken pieces. Each fragment in turn is drilled, beginning one-eighth to one-fourth inch behind its fractured edge, going directly through. Silver wire is used, about the size or possibly a little larger than the lead in an ordinary lead-pencil; it is filed sharp on each end to facilitate insertion. The pieces are drawn together by main force, and the wire is twisted tightly, holding them in apposition; the ends are then cut and the wire is hammered down flat on the bone. The subcutaneous tissues are then sewed down over the bone with heavy catgut; a drainage tube is inserted in the wound, coming out of the most dependent part of the outside of the joint, a small incision having been made on the end of a Tait's forceps pushed down through the original wound, a small bunch of horse-hair drains is then laid across the patella in the same line as the original incision, each end protruding about one inch, the skin is then stitched with silk. The wound is dressed on the third day, and the horse-hair drain removed and possibly the drainage tube; however, the tube may be left in until the second dressing if desirable. After ten days the wound should be entirely healed, and at the end of the second week passive motion should be begun, the patella being daily pushed from side to side, each day more forcibly than the preceding. At the end of the third week flexion should be started and continued daily by the surgeon, until six weeks have elapsed since the time of operation; the patient then should be allowed to use his limb, keeping up the active motion, but carefully, until ten weeks have elapsed since time of operation.

CASE I.—March 2d. William R——, longshoreman, aged forty-three years, single. While working

on one of the city piers, the patient slipped and fell, sustaining a violent jerk to the right knee. Examination showed fracture of the right patella in transverse diameter, attributed to muscular action. Considerable œdema surrounded the joint. The case was treated for five days with the ordinary posterior splint and ice bag. The patient positively refused operation of any kind. Adhesive plaster strips and traction were tried, but the patient would not tolerate it. Plaster-of-Paris dressing could not be endured, and finally treatment was continued with the posterior splint alone. After six weeks absolutely no union had occurred, and the patient still refusing operation was dismissed on account of obstinacy. The patient returned on April 29th and wished to be operated upon. Examination showed the knee in good condition so far as swelling, etc., was concerned, but no union. The patella was wired on May 5th. The patient was addicted slightly to alcohol and the anæsthetic was poorly taken; post-operative temperature rose to 101° F. in twenty-four hours, but soon fell to normal and good general condition ensued; primary union obtained. The wound was dressed and drainage removed on May 9th. Dating from the time of operation, passive motion was begun, from side to side, on the patella at the end of the second week; at the end of the third week, flexion was begun and kept up daily; at the end of the sixth week, the patient was allowed to use his leg alone; after two months had elapsed, he was dismissed with one-half flexion, and afterward regained full use of his limb.

Case II.—June 10th. Michael H——, aged twenty-one years, single, laborer. The patient, a healthy and muscular man, slipped from the edge of the sidewalk into the gutter, and in trying to "catch himself" bent his knee strongly, and the patella parted from muscular action. Examination showed a fracture of the patella with considerable swelling and pain; the fragments could be nearly apposed. Quite a period of time elapsed before the tissues around the joint were thought to be in good enough condition to be operated upon. The operation of wiring was done on June 26th. The anæsthetic was well borne; no elevated temperature followed. Primary union took place; passive motion and flexion were done as in previous case. At the end of the fourth week the patient had but slight flexion, but it gradually increased from day to day until one-fourth flexion was produced, when the patient disappeared.

Case III.—May 24th. George S——, aged twenty-six years, laborer. The patient, an active, healthy man, broke the left patella five years previous to date. It was treated with splints and plaster. He walked in seven weeks. Only ligamentous union occurred; the fragments were four inches apart on account of stretching; there was fairly good motion. The present injury took place from muscular action; he stumbled while going down-stairs. The knee was flexed strongly and the right patella parted. Examination showed considerable effusion in and around the joint, and all the signs of fracture. Ice bags and posterior splint were used until May 29th, when an open operation and wiring were done. Primary union took place; there was no elevated temperature. Passive motion was done, the same as in previous cases. The patient was dismissed on July 15th in good condition, and with one-fourth flexion, which latter was increasing daily.

This last patient sustained a refracture of the patella on August 17th, about one month after being dismissed. He was carefully instructed not to use his limb, and, contrary to all advice, he decided, at a picnic, to outdo all competitors in a flat-foot jumping match. The patella was wired again and his recovery was uneventful. However, the result was not a very good one, he having, when last seen, considerable ankylosis; his obstinacy in disobeying directions was the chief cause of his joint stiffness.

In summing up, it will be seen that the aponeurotic fringe can be removed only by operation; and should such good fortune befall that nothing is interposed at the time of injury, the pressure exerted to control the contraction of the quadriceps seriously interferes with the circulation and causes such intense distress that it is unendurable. We are forced also to see that fibrous or ligamentous union is the best result we can expect from the non-operative means of treatment, and, as said before, this will in time stretch to such a degree that a condition of stumbling is produced, thereby frequently resulting in accident and fracture of the opposite patella.

The operation should not be attempted after the fiftieth year; other contraindications are diabetes and albuminuria. Syphilis, gout, alcoholism, and tuberculosis also call for serious deliberation. However, taking everything into consideration, the writer believes that in most cases, when rigid asepsis can be observed, the wire-suture method is decidedly the best form of treatment.

56 East Twenty-fifth Street.

Some Points in the Examination and Diagnosis of Traumatic Nerve Affections. — D. S. Fairchild says the remote effects of injuries grow in complexity. A factor of very great influence is that of the mind. Psychic complications of railway accidents can scarcely be estimated. Medical men find it more difficult to agree in a case of neurosis than in most other affections. Rules of conduct to be followed by the road's examiner and by the physician in attendance or expert are presented. The successful simulation of organic nerve disease is considered practically impossible. The groups of symptoms presented by traumatic neurasthenia are very complex. Traumatic hysteria is closely allied, and hysterical symptoms at times suggest degenerative changes in brain cells. Hysterical paralysis must be differentiated from that of organic disease. In the former there will be no trophic changes in the muscles and no impairment in the electrical reactions, the patellar tendon reflexes are probably increased, and the ankle clonus is absent. —*The Railway Surgeon*, September 4, 1900.

The Modern Treatment of Fractures and Bone Lesions.—Donald Maclean calls attention to certain considerations which have tended to modify some of the classical canons affecting the treatment of fractures. Repair of bone is analogous to the primeval function of fœtal development. The process of repair is one of growth. He suggests the term "guiding" or "moulding" the products of repair to replace that of "setting the fracture." There is only a limited field of usefulness for the plaster cast in surgery. All methods of permanent retentive appliance are objectionable. Owing to asepsis compound fractures are to-day so little dreaded that the surgeon may even convert a simple into a compound wound for purposes of diagnosis or treatment, and with the hope of better results than under older methods. Subcutanous surgery has become greatly constricted. The *x*-ray makes it now possible to proceed with unfaltering faith in many obscure conditions, especially in fractures near the articulations, and particularly in Colles' fracture. Once reduced, only the simplest retentive measures are required. The severe injury upon surrounding structures is the important element. The only rational treatment for sprains, contusions, etc., is not immobilization, but movement. What is true of Colles' fracture is also true of fractures in general.—*The Clinical Review*, September, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, September 29, 1900.

RATIONAL THERAPEUTICS.

DURING the recent International Medical Congress one of the many speakers who treated the themes in hand referred to the wonderful progress which medicine and surgery had made in recent years along the lines of the prevention and cure of disease. What asepsis had done for surgery, bacteriology had accomplished for medicine. In continuing, however, the orator deplored the lag in general therapeutics which seemingly made the many increased means of diagnosis unavailable by the uncertainty of the action of the new remedies now in vogue. But, after all, when we stare the latter fact in the face, is not the condition what may be expected with our increased knowledge of the limitation of many of the commoner diseases and the impossibility of aborting them on the basis of some of the newer theories of treatment?

Pathology has certainly done much for us in teaching the impracticability of many of the cure-alls that are so frequently and earnestly advocated by optimistic enthusiasts. If we are less hopeful of the enactment of miracles we are certainly the better practitioners in the long run. With an increased knowledge of the laws which govern morbific processes we are becoming less liable to go to extremes in expecting the impossible to happen. Pneumonia, rheumatism, typhoid fever, scarlatina, rubeola, and pertussis run their regular course in spite of our wishes and efforts to the contrary. The incurable diseases still hold their own, and the degenerative conditions which follow their due course still mock our futile endeavors to alter nature's laws.

In the contemplation of this state of affairs, while there is reason for some discouragement, there is certainly a healthful and conservative reaction manifested in our increased dependence upon the now well-recognized curative powers of nature and a becoming recognition of the vital resistance of the individual. In other words, rational therapeutics by stern common-sense methods are replacing senseless polypharmacy. Meddlesome interference is being replaced by the furtherance of nature's effort to throw off the disease. We thus mitigate effects rather than attempt to control causative influences. The cold bathing in typhoid may save the tissue waste resulting from high temperature, but does not abort the fever. The same may be said of pleuro-pneumonia. The curve on the chart is a mere incident in the pathology of that disease as indicating the degree and gravity of the danger. The attempt to cure the malady by antipyretics is like tying down the safety-valve to control the steam pressure. In other self-limited diseases the same principle is involved. We are learning better how to appreciate the significance of the indications of nature in a reasonably helpful way rather than endeavoring to divert or alter them by senseless, forcible, and radical methods.

The longer one is in practice the clearer he understands that meddlesome interference is bad. The old practitioner who said when he came to his wits' ends that he studied the needs of his patient was wise in his day and generation. If his patient was hungry he fed him; if thirsty he gave him drink; if sleepy, even at odd times, he allowed his own theories to rest, while he gave the sufferer an opportunity to do likewise. In these ways he followed nature, and her indications were always in the right direction. If the medicine did not act according to his theory he was wise enough to change his methods; in this way he wisely concluded that the theory did not fit the fact.

The real progress in therapeutics has been made precisely in this direction, and accumulated experience is always on the side of common sense and unbiassed judgment in the interpretation of grand principles. The remedies are mere accessories that aid nature's efforts. It is always a good plan when on a dark road to drive with a slack line and give the horse his head. The theory generally engenders over-confidence in the driver and jerks the animal at the wrong place. We are certainly learning this much on the use of vaunted specifics, that those which promise everything accomplish nothing. Shot-gun prescriptions never show good marksmanship. The trouble has been heretofore to discover which of the particular lot hit the bull's-eye. No single remedy of itself can possibly do everything. The controlling conditions are the complex and oft-times antagonistic receptivities of the patient himself. We note this in the various health cures so plentiful through Europe. The waters get the credit when regular living and proper feeding really deserve it. It is nature speaking through all our so-called infallible remedies. When they can travel together we are always safe on the darkest roads. It is in this direction we seem to be drifting. We may be prescribing fewer remedies, but we are learning to use them to better advantage. We are reconciling the absurdities of hobbyism and ultra-reasoning to the common-sense level of natural laws and more rational methods. The mark is plain enough—the real question of success depends on the greater accuracy of aim.

TO REGULATE THE OSTEOPATH.

WE need not be close observers to know that the eternal charlatan, at present calling himself osteopath, is with us in increasing numbers. A walk through the streets in certain of our good localities will convince any one of the fact, for this particular brand of pre-

tenders, like others of the most ambitious kinds, is not given to hiding his light. Occasionally the signs in the windows will have after the name the letters M.D., indicating that the inmate either has or claims a medical degree. We do not wish to believe, however, that any graduate of a reputable medical school has allowed himself to assist in the exploitation of such an outrageous fad as that which hides behind the word osteopathy, but prefer to think that the assumption of the letters indicating the possession of the degree is merely a part of the game. It is not easy to understand the apparent apathy of the medical profession in this matter, but we are sure that the majority are, individually at least, convinced that it is important. The various county medical societies ought to take up the subject, and try to get an authoritative decision from court or legislature, after proper presentation of the case, as to what an osteopath is and what constitutes practising medicine. The cardinal point, in our opinion, as we have previously pointed out (MEDICAL RECORD, February 10, 1900), depends upon whether one who professes belief in any system, no matter how weird, shall be allowed to decide for himself whether he is to be considered as practising medicine in the eyes of the law or not, with his amenability to law inversely proportional to the inherent absurdity of his professed belief. If such a person is a physician according to strict definition, it is certainly clear enough to convince any one that he should be subjected to exactly the same regulations and requirements as are enforced in the case of graduates of schools legally qualified to confer the medical degree. If he is not a physician in the meaning of the law, he has emphatically no right to examine the sick and injured, to make a diagnosis, to suggest and carry out a course of treatment, and to receive remuneration for his work.

The few decisions before the courts, in this State at least, in which cases of this sort have been considered, do not cover this point, but seem simply to have decided that so-called osteopathy is a form of massage, and that to practise it is not to practise medicine. Such decisions could have been given only after improper and imperfect presentation of the facts to the court. Osteopathy may be, and no doubt is, a form of massage; but if it were proved before the proper tribunal that osteopathy is also the name given to what is claimed to be a system by which many diverse pathological conditions can be diagnosticated, treated, and cured, we fail to understand how the decision that to practise osteopathy is not to practise medicine would hold, or could indeed ever have been given. If it is true that according to law it is only necessary for an individual to call himself an osteopath in order to escape entirely the regulations governing medical practice, then there is a serious defect in the law, and a grave injustice is inflicted upon the graduates of medical schools who are compelled to pass State examinations before they can do what the osteopath does by putting a sign in a window.

It is astonishing to know that the osteopaths are starting "schools" in various parts of the country with the avowed intention of sending forth graduates to practise upon the sick, but that, according to court decisions, in this State at least, they are not going to practise medicine. No effort should be spared to get the various State legislatures to bring the products of these osteopathic schools down to the same level of restriction which is required of the mere graduate of a licensed medical school, so that the former can no longer soar unfettered in the lucrative realms of a specially pernicious form of quackery. We want at present nothing but a provision that the so-called osteopath shall pass the regular State examination in everything but materia medica and therapeutics before he is started on his still-hunt for victims. We do not care what his ideas on materia medica and therapeutics are, not because we do not know that they are absurd and nonsensical, but because we recognize the fact that restriction by law on such subjects is neither desirable nor possible. No legislative committee with any sense of fairness could deny the justice of what we suggest, and we hope to see an attempt in this State to have the matter regulated.

What the public thinks of the osteopath is shown by the prosperity of some specimens, but the public rarely knows what is best for it, and its opinion upon technical subjects is worse than valueless. On some subjects public opinion may be very important, but upon a question like this it is blind, unreasoning, and often dangerous, and needs the guidance of the expert mind to keep it from serious pitfalls. We may be sure that as soon as examining-boards are in a position to ask embryonic osteopaths questions on anatomy, physiology, pathology, and obstetrics, there will be fewer of them where they are dangerous. We do not, as we have said already, want any legislation that seems to involve persecution, but we do want the same treatment for all who wish to have the legal right to direct and supervise the care of the sick, and we will trust to time to eliminate delusions and frauds as they arise. *Fiat justitia, ruat osteopathia.*

ANTI-TYPHOID AND ANTI-CHOLERA INOCULATIONS IN INDIA.

IN support of this method of preventing these diseases, the claim is made by its adherents that the results of inoculation in India have been eminently satisfactory, so much so, indeed, as to lead to the hope that at length a means of successfully fighting two of the most deadly maladies known to man has been discovered. In the MEDICAL RECORD of August 11th it was pointed out that the statistics with regard to the value of the use of anti-typhoid serum, both in India and South Africa, were not sufficiently convincing to confirm such roseate views. This expression of opinion receives further substantiation from the perusal of a parliamentary paper containing a correspondence relating to preventive inoculation against cholera and typhoid in India and published in the *London News*. The correspondence on the anti-cholera inoculation consists of extracts from the sanitary commissioner's reports for 1896, 1897, and 1898. In the 1896 report tables are given which show a greater incidence of attack and death rate among persons under observation who have

been inoculated than among persons who have not been subjected to the treatment; but at the same time the commissioner remarks that its further test is necessary. In 1897, however, the results from inoculation are decidedly discouraging, and the commissioner appears more than ever averse to delivering any definite statement on the matter. He says: "It does not seem that anything can be proved regarding the protective effect of the proceeding." The 1898 report is the most inconclusive of the three, containing but the following few lines relating to the subject: "Anti-cholera inoculations were continued at the coolie depot at Puralia in Bengal, but it is not possible to say how far the inoculation was protective, as there are no complete statistics. If any conclusion is permissible from such figures as are available, it is decidedly in favor of the operation."

So far as inoculation against typhoid is concerned, the experiments in India would seem to have been conducted in a somewhat slipshod fashion, as the viceroy and council reported last year that they regretted their inability to furnish the actual numbers of the inoculated together with the results, as no official records were kept, but that over two thousand men had been inoculated and that in no case had any bad or unfavorable symptoms followed the operation. Further, only a very few of those inoculated contracted typhoid fever subsequently, and with the exception of one case the disease was of a mild character, while in two of the cases the disease was in the stage of incubation when the operation was performed. The commander-in-chief in India said that "it had been conclusively proved to the satisfaction of those who were best competent to judge of the matter, that anti-typhoid inoculation when properly carried out achieved an immunity equal to or greater than that which accrues to a person who undergoes and recovers from an attack of that disease."

From the foregoing reports it will be gathered that in India at least neither anti-cholera nor anti-typhoid inoculation has been attended with a marked degree of success. Statistics from South Africa at the end of the campaign should tend to settle the question as to the efficacy of anti-typhoid serum.

News of the Week.

Medical Society of the State of Pennsylvania.—The fiftieth annual meeting of the Medical Society of the State of Pennsylvania was held at Wilkesbarre on September 18th, 19th, and 20th. After the society had been called to order by the president, Dr. George W. Guthrie, prayer was offered by Rev. E. C. Mogg, D.D. Addresses of welcome were delivered by Hon. F. M. Nicholls, mayor of Wilkesbarre, and by Dr. H. M. Neale, of Upper Lehigh, president of the Luzerne County Medical Society. The address in medicine, by Dr. Thomas Turnbull, Jr., of Allegheny, was read by Dr. Adolph Koenig. Dr. Charles Rea read a paper on "The Diagnosis and Treatment of the Early Stage of Pulmonary Tuberculosis"; Dr. W. H. Hartzell, of Allentown, one entitled "Old-Time Treatment and Result of Typhoid Fever"; Dr. T. D. Davis, of Pittsburg, one entitled "Lecturing not Teaching"; Dr. J. C. Bateson, of Scranton, one on "The Human Temperaments and their Application in Medicine"; Dr. J. Emmet O'Brien, of Scranton, one entitled "Analogies between Nervous and Electric Mechanisms"; Dr. Edwin Rosenthal, of Philadelphia, one on "The Treatment of Pneumonia with Antipneumonic Serum"; Dr. Thomas C. Ely, of Philadelphia, one entitled "A Case of Meningitis Complicating Pneumonia"; Dr. Judson Daland, of Philadelphia, one on "Raynaud's Disease"; Dr. J. Montgomery Baer, of Philadelphia, one on "The Diagnosis of Ectopic Pregnancy." On the second day Dr. Walter Lathrop, of Hazleton, delivered the address in surgery. Dr. Charles H. Miner, of Wilkesbarre, read a paper on "The Etiology of Typhoid Fever"; Dr. H. A. Hare, of Philadelphia, a paper on "The Complications and Sequelæ of Typhoid Fever," and Dr. Alfred Stengel one on "The Treatment of Typhoid Fever." Dr. William H. Dudley, of Easton, read a paper entitled "The Question of the Enforcement of the Medical Laws of the State of Pennsylvania." Dr. T. M. T. McKennan, of Pittsburg, read a report of some medico-legal cases. Dr. Thomas J. Mays, of Philadelphia, presented a communication entitled "Four Phthisical Remedies which Have Proved Most Valuable in My Experience." At the afternoon session Dr. Mordecai Price, of Philadelphia, read a paper entitled "Appendicitis and its Treatment." Dr. Charles P. Noble, of Philadelphia, gave the address in obstetrics. Dr. Gwillym G. Davis read a paper on "Applied Anatomy; its Value and Place in the Medical Curriculum"; Dr. O. C. Gaub, of Pittsburg, one on "The Surgery of the Gall Bladder," and Dr. Evan O'Neill Kane, of Kane, described a removable buried suture for abdominal incisions. Dr. F. P. Ball, of Lock Haven, presented a communication on "Tuberculosis of the Bladder." Dr. J. C. Dunn read a communication entitled "Silver Nitrate in Dermatology." Dr. L. J. Hammond, of Philadelphia, read a paper on "Primary Tuberculous Adenitis — its Surgical Treatment"; Dr. W. M. Beach, of Pittsburg, one on "Constipation or Obstipation and its Practical Treatment"; Dr. Charles L. Leonard one on "Surgical Diagnosis by the Roentgen Method," and Dr. A. A. Eshner, of Philadelphia, a paper entitled "Paralysis Agitans Without Tremor." The following officers were elected for the ensuing year: *President*, Dr. Thomas D. Davis, of Pittsburg; *First Vice-President*, Dr. W. B. Ulrich, of Chester; *Second Vice-President*, Dr. L. H. Taylor, of Wilkesbarre; *Third Vice-President*, Dr. A. A. Eshner, of Philadelphia; *Fourth Vice-President*, Dr. M. L. Herr, of Lancaster; *Secretary*, Dr. C. L. Stevens, of Athens; *Assistant Secretary*, Dr. W. L. Pyle, of Philadelphia; *Treasurer*, Dr. G. B. Dunmire, of Philadelphia; *Chairman of the Committee of Arrangements*, Dr. John H. Musser, of Philadelphia. The next meeting will be held at Philadelphia, beginning the third Tuesday in September, 1901. The proceedings of the third day included the following papers: Ad-

dress in hygiene, by Dr. Joseph T. Rothrock, of West Chester; "Recent Advances in the Bacterial Purification of Sewage," by Dr. D. H. Bergey, of Philadelphia; "The Rôle of Insects in the Transmission of Disease," by Dr. Emma O. Cleaver, of Reading; "Humanology, or Higher Physiology," by Dr. E. N. Ritter, of Williamsport; "Sanitary Milk for Children," by Dr. B. H. Detwiler, of Williamsport; "The Use and Abuse of the Forceps," by Dr. W. Knowles Evans, of Chester; "A Further Report on the Cataphoric Treatment of Cancer," by Dr. G. Betton Massey, of Philadelphia; "The Present Status of Ovarian Organo-Therapy," by Dr. Wilmer Krusen, of Philadelphia; "Nausea and Vomiting of Pregnancy," by Dr. John M. Batten, of Downington; "Paroxysmal Delirium — a Short Study in Auto-intoxication," by Dr. W. C. Hollopeter, of Philadelphia; "Nephritis as a Complication in Gynæcological Disease," by Dr. George Erety Shoemaker, of Philadelphia; "Myocarditis," by Dr. John H. Musser, of Philadelphia; "Report of Two Cases of Ovarian Hydrocele," by Dr. Reed Burns, of Scranton; "Do We Resort too Frequently to Surgical Operations?" by Dr. Richard H. Gibbons, of Scranton. Address in ophthalmology, by Dr. Charles McIntire, of Easton; "The Electro-Magnet in Eye Surgery, with Demonstrations; and Report of a Number of Cases," by Dr. Edward B. Heckel, of Pittsburg; "A Plea for the Earlier Recognition of Squint in Children by the Family Physician, and the Earlier Application of the Methods of Treatment," by Dr. C. A. Veasey, of Philadelphia; "The Relation of the Oculist and Optician to the Profession and the Public," by Dr. P. J. Kress, of Allentown; "Surgical Intervention in Purulent Discharge of the Ear," by Dr. Joseph E. Willetts, of Pittsburg; "The Climatology of Neurasthenia," by Dr. F. Savary Pearce, of Philadelphia; "Traumatic Hysteria, with a Report of Cases," by Dr. Edward E. Mayer, of Pittsburg; "The Simplest and Best Method of Removing the Third Tonsil or Post-Nasal Adenoids," by Dr. Louis J. Lautenbach, of Philadelphia; "Living Animal Organisms in the Ear," by Dr. Francis R. Packard, of Philadelphia; "The Passing of the Galvano-Cautery," by Dr. Charles P. Grayson, of Philadelphia; "Leukæmia and Pseudo-Leukæmia, with Presentation of Patients," by Dr. Charles H. Miner, of Wilkesbarre; "The Operative Treatment of Ugly Ears," by Dr. John B. Roberts, of Philadelphia; "Typhoid; its Etiology, Course, Treatment and Pathology; Concisely Considered," by Dr. James Fulton, of New London; "The Treatment of Œsophageal Stricture, with Particular Reference to the König Method," by Dr. Charles H. Frazier, of Philadelphia; "What I Have Learned from a Personal Experience of Thirty-two Bottini's Operations in the Radical Treatment of Hypertrophy of the Prostate Gland," by Dr. Orville Horwitz, of Philadelphia.

Suicides in the French Army.—A despatch to the New York *Times* states that suicides are becoming of shocking frequency in the French army, and it is no secret that it is the result of the insupportable treatment which the soldiers are subjected to and the general brutalizing condition of life which they are compelled during three years to lead. Three suicides having occurred in one week in a single regiment, the colonel has issued an order of the day declaring that suicides will henceforth be treated as deserters, and that no military honors will be rendered them at their funeral. No man, it concludes, who is a real patriot will commit suicide; but nothing is said concerning the non-commissioned officers whose brutal treatment has caused these suicides.

Pathological Society of Philadelphia.—At a stated meeting held on September 13th, Dr. J. Dutton Steele exhibited a specimen of hour-glass stomach and sections of endothelium of the lung and retroperitoneal glands. Nominations for officers for the ensuing year were made.

The Congress of Scandinavian Ophthalmologists, which has been organized on the model of the Ophthalmological Congress annually held at Heidelberg, recently held its first meeting at Stockholm. The meetings are to be held every two years; the next will be held in Copenhagen in 1902.

The Medical Association of Hawaii.—At the last annual meeting of this association the following officers were elected: *President*, Dr. W. E. Taylor; *Vice-President*, Dr. H. E. Sloggett; *Secretary and Treasurer*, Dr. G. A. Hodgins. The executive committee consists of the officers and Drs. R. P. Myers and C. B. Cooper.

Instruction in Tropical Diseases, stimulated by the good work of the two British schools and under the growing conviction that the world's work in the twentieth century is to be the enlightenment and elevation of uncivilized man, is becoming general in all the countries of Europe. In the University of Bordeaux M. Le Dantec, who has for several years lectured privately on that subject, has just been appointed to give a course of instruction on tropical diseases. In Holland the teaching of tropical medicine has recently been inaugurated by Dr. J. H. Kohlbrugge, Privat-docent in the University of Utrecht.

Inebriety among Women.—At the recent annual convention of the Connecticut Catholic Total Abstinence Union, the president stated in his address that while habitual intemperance among men was decreasing, alcoholism among women was becoming more common. This statement receives startling confirmation as regards England by the fact revealed by a parliamentary report on the working of the Inebriates Act, under which magistrates are able to commit habitual drunkards to reformatories, that of ninety-two such commitments ninety were of women. Of six inebriate reformatory institutions existing in Great Britain, no less than five are for women.

A New Diet Sect.—The daily papers report the establishment in Chicago of a new association of oddities who believe that eating raw food is the secret of longevity, perfect health, superior mental vigor, amiability of disposition, and economical living. They contend that the cooking of food is in opposition to nature's laws, and that it is only a fad which

originated somewhere in the early ages of man, and that since then humanity, mentally, morally, and physically, has been steadily on the decline. All the adherents to the new belief have discarded from their tables every edible that has felt the influence of fire. They say fire destroys all that is life-giving and healthful in food. Their diet list includes such toothsome dainties as dried beef, raw carrots and raw oats, wheat, and rice flour.

Fire at Roosevelt Hospital.—An explosion of benzin used by painters in a brick building adjoining Roosevelt Hospital caused a small fire there last week. The building was used as the stable and morgue. The fire caused little damage.

A Kentucky Feud.—There is trouble over the proposed celebration of the semi-centennial of the Kentucky School of Medicine in the present year, a former member of the faculty asserting that the college is not fifty years old, and also that it is not the lineal descendant of and legitimate successor to the medical department of Transylvania University.

Physicians Sued.—A suit for $10,000 damages has been brought against two physicians in New Brunswick, N. J., by a man who claims that he was wrongly incarcerated in an insane asylum on a certificate signed by them. He was released in three days, and asserts that his seizure and detention were the result of a conspiracy to which the accused physicians were party.

The American Association of Obstetricians and Gynæcologists.—At the annual meeting of this society, held last week in Louisville, the following officers were elected: *President*, Dr. W. E. B. Davis, of Birmingham, Ala.; *Vice-Presidents*, Dr. Edwin Walker, of Evansville, Ind., and Dr. A. Goldspohn, of Chicago; *Secretary*, Dr. William A. Potter, of Buffalo, N. Y.; *Treasurer*, Dr. Xavier O. Werder, of Pittsburg, Pa. Cleveland, O., was selected as the place of the next annual meeting.

The Pan-American Medical Congress.—Dr. Tomás V. Coronado, secretary, announces that the third Pan-American Medical Congress will be held in Havana, Cuba, on Wednesday, Thursday, Friday, and Saturday, December 26, 27, 28, and 29, 1900. The official languages of the congress will be French, Spanish, Portuguese, and English, though naturally the greater number of the papers and addresses will be in Spanish. Several of the steamship lines running to Havana announce a rate of one fare for the round trip, and the Southern Passenger Association has established a rate of one fare plus $2 to Havana and return.

A Hospital Interne Suspended.—The commissioner of charities has suspended one of the internes of the Metropolitan Hospital on Blackwell's Island for thirty days on the charge of negligence. A consumptive had been turned out of the hospital in a dying condition, on the statement of the physician that he was not a proper subject for hospital treatment. The superintendent accepted the physician's report and discharged the patient. In his order suspending the physician the commissioner also reprimanded the acting superintendent, who, he said, either did not know what a hospital was for, or had a distorted idea of the purpose for which the tax-payers support the Department of Charities. Under no circumstances, the commissioner said, was there any excuse for turning any one away as this dying patient had been. Henceforth, he ordered, the physician in charge shall personally examine every patient and see for himself if his condition is such as to warrant discharge.

Drowned in Two Inches of Water.—An epileptic in Jersey City was seized with a convulsion and fell face downward in a puddle of water only two inches deep, and when found was dead from suffocation.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 22, 1900. September 14th.—Surgeon C. T. Hibbett detached from the Cavite naval station and ordered to the *Newark;* Surgeon O. D. Norton detached from duty with the marine regiment in China and ordered to the *Monadnock;* Assistant Surgeon F. L. Benton detached from the naval hospital, Cavite, P. I., and ordered to the *Brooklyn.* September 18th.—Medical Director J. A. Hawke detached from the New York navy yard October 1st, and ordered to duty at the naval hospital, Mare Island, Cal.; Medical Inspector G. P. Bradley detached from the naval hospital, Mare Island, Cal., on reporting of relief, and ordered home and to wait orders. September 21st.—(Orders issued by commander-in-chief of Asiatic station.) Passed Assistant Surgeon G. D. Costigan detached from the *Newark* and ordered to the *Yorktown;* Assistant Surgeon E. Davis detached from the *Yorktown* and ordered to the Cavite naval station.

The Coal Companies' Doctors.—One of the grievances of the striking miners in the anthracite regions is that they have to pay for the services of a "company doctor" whether they like him or not. Concerning this a correspondent of the *Commercial Advertiser* writes that "the 'company doctor' is in many sections of the Pennsylvania coal regions a worthy and serviceable man who stands well with the miners. In other sections, however, he is a detested bugaboo, whom the miners have to pay for, but seldom see. Sometimes the miners are required to pay a certain amount each month for 'general sanitary supervision.' Such payments they resent bitterly, for few of them comprehend the meaning of the service charged for. In most mining settlements, however, the doctor makes his own charges for personal service, and in such cases he would be regarded as a very acceptable man in the community if the mine owners did not compel the miners to pay him. A coal miner is very much like the average citizen in his sentiments toward a doctor's bill." This grievance, however, like the companion one of the "company store," is a purely local one, and very few of the large mining companies maintain either the one or the other system.

Obituary.

LEWIS ALBERT SAYRE, M.D., LL.D.,

NEW YORK.

Dr. Sayre died at his home in this city on September 21st, at the age of eighty years. He had been in failing health for some time, but suffered no pain and retained his faculties to the last. He was born in Battle Hill, now Madison, N. J., on February 29, 1820, and the infrequency of his birthdays was an unfailing source of witticisms by himself and his friends; he always said that he hoped to live to see his twentieth birthday which would not be until 1904. His father was a well-to-do farmer of Morris County, N. J., and his grandfather was a quartermaster in the revolutionary army. During Lafayette's visit to this country in 1825, little Sayre was chosen on one occasion to recite some verses of welcome before the distinguished visitor. His early education was received in a local school and at Wantage Seminary in Deckertown, N. J., and his collegiate course was passed at Transylvania University in Lexington, Ky. In opposition to the wishes of his uncle with whom he lived at Lexington, who wanted him to study for the ministry, he came to New York and entered the College of Physicians and Surgeons, from which he was graduated in 1842. For ten years following his graduation he was prosector of anatomy at the college under Dr. Willard Parker. He was appointed surgeon to Bellevue Hospital in 1853, and to the Charity Hospital on Blackwell's Island in 1859, and had remained since 1873 a consulting surgeon to both these institutions, as well as to St. Elizabeth's Hospital and the Home for Incurables.

He was one of the founders of the Bellevue Hospital Medical College in 1861, and was a member of its first faculty as professor of orthopedic surgery, fractures, and luxations. He continued to fill this chair, later designated as that of orthopedic surgery, until 1898, when the college was united with the New York University. He then became emeritus professor of orthopedic surgery in the consolidated institution. He was also one of the founders of the New York Academy of Medicine, the New York Pathological Society, and the American Medical Association. He was elected vice-president of the latter in 1866, and became its president in 1880.

In 1860 Dr. Sayre was appointed "resident physician," or health officer, of New York, and accomplished much in the way of the sanitary betterment of a city which sadly needed it at that time. He held the office continuously during the terms of three succeeding mayors, and his annual reports pointed out a series of possible reforms that are still being acted upon. They included the first suggestions of several sanitary measures which are now regarded as matters of course, and others the necessity of which is not yet fully appreciated. These reports dealt with smallpox, sewerage, lighting and ventilation of tenements, and the possibility of preventing the incursion of cholera by quarantine regulations, which was an original idea with him, and one whose truth has been abundantly proved. He also served as surgeon in the militia from 1844 to 1866.

But the fame acquired by Dr. Sayre as a sanitarian was outshone by his brilliant reputation as a bold and original surgeon. He was the first American to perform successfully an exsection of the hip for morbus coxarius, his first operation having been in 1854. During the medical congress in Philadelphia in 1876 he demonstrated the operation before a number of visiting surgeons, one of whom, Lister, said that the privilege of witnessing that operation was in itself a sufficient reward for the fatigues of the voyage across the Atlantic. Dr. Sayre had, four years previously, visited Europe and lectured on the treatment of hip-joint and spinal disease before a number of medical societies. In 1877 he again went to England as a delegate for the American Medical Association to the meeting of the British Medical Association in Manchester, and demonstrated there and elsewhere in Great Britain the use of suspension and the application of the plaster jacket in the treatment of Pott's disease of the spine. His contributions to medical literature were many, and as a lecturer he was renowned. In recognition of his many and great contributions to surgery, especially orthopedic surgery, Dr. Sayre was made an honorary member of the British Medical Association, the Medico-Chirurgical Society of Edinburgh, the Surgical Society of St. Petersburg, and the Medical Society of Norway. Charles IV. of Sweden also decorated him with knighthood of the Order of Wasa for his attendance on a member of the royal family.

Of three sons, all graduates in medicine, Dr. Reginald H. Sayre, of this city, is the sole survivor.

Dr. Sayre was a typical American in every sense. Ingenious, original, and resourceful, he was ever ready to do and dare in any surgical emergency. Few in his time commanded wider and more extensive appreciation of his work, and no American surgeon enjoyed a better reputation than did he whose name and fame belonged to the entire civilized world of progressive science.

At a special meeting of the executive committee of the New York County Medical Association, held September 24, 1900, the following resolutions were unanimously adopted:

Whereas, It is our sad duty to announce the death on September 21, 1900, of our late associate, Dr. Lewis Albert Sayre, one of the founders of the American Medical Association, and its president in 1880; therefore be it

Resolved, That we place on record our high appreciation of the valuable services which he has rendered to medicine and surgery during his long and useful life;

Resolved, That his daring originality, his freedom from surgical traditions, along with his unflagging enthusiasm and interest in everything pertaining to his beloved profession, constituted him a teacher of rare excellence, whose pupils will cherish his memory long after the voice of their preceptor is hushed;

Resolved, That we extend, in the name of the members of the New York County Medical Association, our heartfelt sympathy to the afflicted relatives, and direct that a copy of these resolutions be sent to the family and to the medical journals.

Obituary Notes.—Dr. James Hart Curry died on September 24th at his home in Shrub Oak, N. Y. He was born in this city in 1827, but had lived at Shrub Oak nearly all his life. He studied at Peekskill Military Academy, and was graduated from the Yale Medical School in 1852. He was the oldest member of the Westchester County Medical Society, and had held every office in that society. He was a member of the State Medical Society, and the Yale Medical Alumni Association, of which he was the third president. He served as surgeon of the Eighteenth Regiment, New York volunteers, in the civil war, and later was surgeon of the Fifth Division, N. G. S. N. Y., on the staff of the late Gen. James W. Husted.

Dr. Richard H. White, of this city, died on September 22d in Sullivan County, where he had gone for his health, pulmonary tuberculosis being the cause of his death. He was a native of Canada, and was a

graduate in arts of the University of Toronto and in medicine of Trinity Medical College in 1891. In his practice he had devoted himself chiefly to pulmonary diseases.

Dr. William H. Munn, of this city, died on September 24th of congestion of the brain. He was fifty-one years of age, and was a graduate of the University Medical School in New York in the class of 1868.

Dr. Preston B. Scott died at his home in Louisville, Ky., on September 24th, aged sixty-eight years. Dr. Scott was a graduate in medicine of the University of Louisville in the class of 1858, and served as surgeon in the Confederate army during the civil war. He was a member of the American Medical Association and of the Kentucky State Medical Society, and at the time of his death was president of the Association of Surgeons of the Confederate Army and Navy, having been elected to that office at the third annual meeting of that society, held in Louisville early in the summer.

Dr. Henry L. Smyser, the oldest physician of York, Pa., died in that city on September 16th, at the age of seventy-five years. He was graduated from the University of Pennsylvania in 1847, but in 1849, seized with the gold fever, he went to California, returning in the course of two years. In 1856 he became attached to the Russian army as surgeon-major, and served through the Crimean War. On returning to the United States he enlisted in the Union army and served throughout the War of the Rebellion as contract surgeon at York barracks.

Dr. James Willoughby Phillips, superintendent of Burn Brae Sanitarium at Clifton Heights, Pa., died September 19th, at the age of fifty-three years. He was a graduate of the University of Toronto and a fellow of the Royal College of Surgeons.

Progress of Medical Science.

New York Medical Journal, September 22, 1900.

The Treatment of Chronic Cystitis in the Female by Curettement of the Bladder and Instillations of Corrosive Sublimate.—C. G. Cumston does not consider it necessary or possible to curette the entire surface of the vesical mucosa through the urethra, as the lesions show a marked preference for only the trigonum, around the mouths of the ureters, neck of the bladder, and posterior urethra. In a general way we may commence in the adult with a solution of 1:4,000 and in the child 1:5,000. Two to four cubic centimetres make a sufficient quantity with from ten to fifteen drops in the neck of the bladder and posterior urethra. He describes the special instruments which he prefers and the progressive steps of the operation. His conclusions are as follows: (1) Sublimate instillations will often produce a very great improvement in the distressing symptoms met with in both tuberculous and non-tuberculous cystitis, such as a diminution in the frequency of micturition, a decrease of the pain, an increase in the capacity of the bladder, and an improvement in the condition of the urine. In some cases a complete cure may be obtained. (2) When the instillations fail to produce the desired effect, curettage of the bladder is indicated in both tuberculous and non-tuberculous cystitis. (3) In gonorrhœal cystitis instillations of sublimate are particularly efficacious and rapidly subdue the pain. (4) Under favorable circumstances a radical cure of primary tuberculous cystitis may be obtained by curettage when the vesical lesions are localized and the kidneys free from the disease. Curettage per urethram will not allow the surgeon to reach the entire surface of the bladder, so that when the lesions are extensive they should be directly treated by suprapubic cystotomy. (5) Much relief may be afforded by curettage to a large number of patients suffering from tuberculosis of the bladder, but who on account of the advanced stage of generalized infection are in no condition to undergo a more radical operation. (6) When cystitis is due to a prolapsus of the genital organs, and when hysteropexy, combined with anterior and posterior colporrhaphy, does not relieve the bladder symptoms, curettage of the bladder, followed by sublimate instillations, is the proper treatment.

A Report of Three Cases due to Ascending Urinary Infection due to the Bacillus Pyocyaneus and the Proteus Vulgaris.—By G. Blumer and A. J. Lartigau. Case I. showed symptoms referable in the main to the nervous system, the most important of these being partial paraplegia and exaggerated reflexes succeeded by complete paraplegia, loss of reflexes, anæsthesia, and analgesia. No lesion of the cord was present. On autopsy, evidences of an old affection of the bladder were found upon which was superimposed a fresh inflammation, and it is probable that this was the route of infection. A bed-sore developed, and this became infected with bacillus pyocyaneus. Case II. followed a stone in the bladder. Case III. presented the clinical features of a hemorrhagic septicæmia, probably incidental to puerperal streptococcus infection.

Membraneous Enteritis.—H. F. Slifer gives the clinical history of a case with a brief outline of the general features of the malady.

The Boston Medical and Surgical Journal, Sept. 20, 1900.

Knee-Joint Surgery for Non-Tuberculous Conditions.—Joel E. Goldthwait reports thirty-eight operations for synovial fringes, injured semilunar cartilage, loose cartilage, coagula, exploratory incision, etc., and judging from the results obtained holds that operations upon joints need not be feared more than operations upon other parts of the body. He urges the importance not only of operating to relieve a definitely recognized condition, but also of making use of exploratory incisions in doubtful cases to determine the exact nature of the disease. Without this, it is impossible in many cases to differentiate in the incipient stage between several different conditions, and it is at this very time that the most can be accomplished in the way of treatment if the exact condition is known. No unpleasant results followed the operation except in one, a case of osteoarthritis, in which the disease was apparently made more acute. The exploratory incision, with this one exception, did not alter the course of the disease. The cases from which the semilunar cartilage was removed have functionally normal joints. The cases in which the synovial fringes and coagula were removed are improved in proportion to the nature of the disease which caused the condition to be present.

Fat-Free Tincture of Digitalis.—Elbridge G. Cutter calls attention to this preparation, devised and used in the Philadelphia Hospital to meet the serious drawback of bulk in the use of the infusion of digitalis, and to obtain a preparation which would not nauseate. A still more valuable feature of the remedy is the rapidity with which the preparation is absorbed and assimilated in comparison with the official product. The time element of direct action is a very important matter in some cases, and might readily mean the difference between the life and death of a patient. No especial difference in the time of absorption between hypodermic injections and mouth administrations is observable, but when the tincture is given hypodermically the pulse reduction seems to be greater with the fat-free tincture, though not extending over any greater length of time. Directions are given for the preparation of this tincture.

Treatment of Pott's Disease after the Development of the Deformity.—By Edward H. Bradford and F. J. Cotton.

Journal of the American Medical Ass'n, Sept. 22, 1900.

Trauma as a Cause of Nervous Diseases.—C. W. Burr speaks solely of the causative influence of trauma and of the various ways in which it acts, and considers only the organic and functional diseases unaccompanied by serious external injury. It is not safe to say always that because a disease follows a trauma it is the result. It is generally accepted that trauma without injury to the skull or spine may produce organic disease referable to the brain or cord. Certain functional nervous diseases may result from accident. It is difficult to prove that trauma is a cause of locomotor ataxia. Hysteria and neurasthenia frequently follow an accident, and are sometimes quickly recovered from after legal settlement. In hysteria there is no discoverable lesion. Serious physical injury is rarely followed by hysteria. It is doubtful if the attempt to group together certain symptoms under the term traumatic neurosis serves any good purpose.

Medico-Legal Relations of Traumatic Nervous Affections.—J. H. Lloyd gives a case as a text for his paper. After a fall downstairs there was immediate paralysis of body, legs, and arms, presenting the picture of total transverse lesion in the middle cervical region. Death took place in five days. The chief lesion was a small hemorrhage involving principally the anterior halves of the posterior columns. The microscope, however, showed extensive destruction of the

essential elements of the medullary tissue, involving the whole transverse area of the cord. Abolition of function in these traumatic cases is accounted for by necrotic organic changes in the neurons. Most, if not all, obdurate symptoms represent changes in the organic bases. They are none the less real because they cannot be seen without the microscope. Functional diseases causing disablement are entitled to the same consideration as the more imposing "organic" affections.

Prognosis and Treatment of the Traumatic Neuroses.—W. Skinner seeks to determine what is meant by traumatic neurosis, and discusses prognosis. Some make a distinction between the neuroses and traumatic neurasthenia and hysteria. Neuroses include all. Heredity and previous health should always be inquired into. Litigation has a great influence tending to self-concentration and magnifying of symptoms, which increase in severity. Simulation is held to be rare by neurologists, and exaggeration frequent, while railway surgeons believe the former common and traumatic neurosis an imaginary disease. The truth lies between. Rest treatment is the best. Prince is quoted to the contrary. Rigid isolation should be insisted upon. If this fails, there should be complete change of climate and scene. Hydrotherapy is of great utility. Drugs are of comparatively little value.

Traumatic Neuroses from the Standpoint of a Surgeon.—A. D. Bevan says the medical attendant is chiefly responsible for the condition of so-called traumatic neurosis. It is a mental state, not an organic disease, and he illustrates his point with cases. Without positive and immediate symptoms of gross lesion, malingering, or abnormal cerebral state, traumatic neuroses or a mixture of the two are present. In traumatic neuroses there are two factors: a brain readily affected by suggestions; suggestions furnished by an accident. Refined means of diagnosis—dynamometer, æsthesiometer, and electricity—are seldom of value. Recovery may be indefinitely postponed under improper surroundings and advice. No secondary degenerations of the nervous system follow traumatic neuroses.

The Identification of Dextrose in Human Urine.—By H. Stern.

Physicians as Speakers.—By William Whitford.

Specialism in Medicine.—By F. C. Shattuck.

Medical News, September 22, 1900.

Toxicity versus Septicity in the Infectious Pathogenic Bacteria.—Eugene Wasdin says in such diseases as typhoid fever and gonorrhœa, in which the infection may take place from the mucosa of some organ other than the respiratory tract, the septic quality will be as readily followed by sepsis as from infections along this tract. The law, then, in these acute types of cases encountered in all of them, is that the infection having taken place, the type of the disease must depend upon the development in the infecting organisms of the inherent qualities of toxicity and septicity; that if toxicity preponderate there will result the toxæmiæ, and if septicity be the more pronounced the septicæmiæ will be produced, since these qualities coexist in each infective germ, the one or the other being exhibited in greater perfection according to environment.

Total Extirpation of the Ureter.—Willy Meyer speaks of the operation at the time of nephrectomy or subsequently. He gives two personal cases. The three indications for nephrectomy and their influence upon a probable extirpation of the ureter are discussed; tumor, tuberculosis, and pyonephrosis. The operation is described.

Studies in Surgical Technique, with a Report on Operative Surgery at the City Hospital for 1898 and 1899.—By George Emerson Brewer.

Philadelphia Medical Journal, September 22, 1900.

Chronic Ear-Vertigo (Ménière's Disease); its Mechanism and Surgical Treatment.—H. Burnett says that inasmuch as the essential cause of chronic ear vertigo is the impaction of the stapes in the oval window, removal of this retractive force and liberation of the stapes will cure the disease. He therefore advises the removal of the incus, which breaks the retractive force of the tensor tympani and malleus exerted through the incus upon the stapes, and the latter bonelet is liberated. In chronic purulent cases it is necessary to excise the remnants of the diseased membrana, and the malleus and the incus, with their synechial bands, in order to liberate the stapes. This operation in such cases, supplemented by local treatment of the purulent drum cavity, is followed by cessation of the vertiginous attacks, and cure of the chronic purulency. Thus excision of the diseased ossicles leads to curing the chronic purulency and acts as a prophylaxis of antrum and mastoid disease. The operation is described in full.

Acute Seminal Vesiculitis.—By H. H. Morton. The author's treatment is as follows: The patient is put to bed and given a saline cathartic, which is always in order in every pelvic inflammation. Hot sitz-baths and copious irrigations of the rectum with hot water are useful in allaying the inflammation. If the posterior urethritis is severe, sandal-wood oil relieves the tenesmus and renders the urine less irritating. Injections into the anterior urethra of course are contraindicated, but above all things any attempt at massage or stripping the vesicles should be absolutely interdicted. Under this plan of treatment most cases of acute vesiculitis will recover in from two to four weeks.

Multiple Metastatic Sarcomata of the Lungs.—By S. S. Burt.

The Lancet, September 15, 1900.

Thrombosis in the Veins of the Pelvis and Lower Extremities after Operations.—By K. G. Lennander. The author makes a strong plea for the elevation of the foot of the bed after operations. He says that if we wish to prevent the formation or spreading of a thrombus it is necessary to combat all causes of local stasis. For the pelvic and lower extremity veins the raising of the lower end of a patient's bed should be of considerable mechanical assistance in promoting the flow of blood toward the inferior vena cava and right auricle. The value of this aid may be increased and the patient made more comfortable by frequently altering his position in the bed, and lightly rubbing the feet and legs, provided that he has not already a thrombus. If any varices exist on the distal side of the operation wound in a lower extremity the part should be bandaged from the foot to such a point, the leg should be elevated, or, better, the bed should be raised. This procedure exerts a very much more noticeable influence upon the circulation. By its use he believes we may largely prevent thrombosis following surgical operations, parturition, and those diseases which are accompanied by intense anæmia and auto-intoxication, in which a tendency toward the complication of thrombosis exists.

Heat-Stroke in India; an Examination of Some Statistics Relating Thereto.—W. J. Buchanan presents statistics of the British army in India showing that heat-stroke is most fatal and most prevalent where the heat is greatest and most oppressive and at the time of year when these influences are at their maximum. It will require much more evidence than has yet been produced to make those who have had experience of the disease in India accept a microbial or any other cause which seeks to minimize the great and predominating influence of fierce and continuous heat While looking upon heat as the most important factor we must also bear in mind the great influence of the usually mentioned predisposing causes, as age, length of residence in the tropics, occupation, exposure, unsuitable clothing (as the tight-buttoned and belted uniform of soldiers), intemperance (perhaps especially beer-drinking), over-fatigue and overcrowding, want of ventilation, and previous illnesses.

A Case of Total Gastrectomy.—By Viera de Carvalho. The patient was a Brazilian woman aged forty-six years, who suffered acute gastric pains after eating and vomited freely. At times blood was raised. A tumor was found in the right epigastric region close to the costal margin. A diagnosis of malignant growth of the pylorus was made and an operation begun for gastro-enterostomy. The tumor was found as expected, but there were adhesions to neighboring organs affecting the greater part of the gastric lymphatics. It was therefore decided to remove the entire stomach. This was done by Carvalho, who describes the operation in detail. The patient was doing finely on the ninth day, the superficial wound having healed. Her appetite was ravenous, and she was able apparently to digest small quantities of solid food.

Poisoning by Carbon Monoxide.—Two cases are described by C. B. Elgood, one proving fatal. He advocates the use of artificial respiration, which employed alone is not free from danger, but which should be accompanied by oxygen inhalations, slapping and friction over the cardiac region, and faradization of the phrenic nerves.

General Nervous Shock, Immediate and Remote, after Gunshot and Shell Injuries in the South African Campaign.—By M. I. Finucane.

Tuberculous Lesions from a Clinical Point of View.—By E. Owen. Address before the Canadian Medical Association.

Hysterical Somnolence and States of Double Consciousness.—By Ethel M. N. Williams.

Prevention and Treatment of Post-Partum Hemorrhage.—Address by J. W. Byers.

The Chemical Examination of the Gastric Contents.—By F. Shufflebotham.

British Medical Journal, September 15, 1900.

An Address on Tuberculous Lesions from a Clinical Point of View.—Edmund Owen, in his address before the Canadian Medical Association, stated that there are three important facts of which the public must be made conscious: first, that the disease is communicable; second, that it is preventable; and third, that it is curable. Tuberculosis is not of the intractable nature it was formerly considered to be. At the end of the nineteenth century it is somewhat unusual for a patient with any surgical affection to be allowed the opportunity of showing what he can do without submitting himself to operation. The following disconnected statements are based upon clinical observation: (1) Chronic inflammation of a joint in a child or young person is always tuberculous—except in those very rare cases in which it is due to hereditary syphilis or osteo-arthritis. (2) Tuberculous inflammation may completely destroy a joint, and then leave it solidly and soundly synostosed, without the surrounding tissues or the skin having been implicated. (3) If tuberculous granulation tissue breaks down into a fluid, that fluid is not pus, and the collection is not, properly speaking, an abscess—unless, by bad fortune, or by worse surgery, it has become infected by septic micro-organisms. (4) The fluid collection is not to be treated as an abscess—by incision and drainage, that is—but is to be opened and emptied, and scraped and cleansed of its unhealthy lining of granulation tissue. Then the wound in the skin is to be completely closed by sutures; firm pressure is to be evenly applied, and the part is to be kept absolutely at rest. The success attending this line of treatment leaves, as a rule, little to be desired, and for this important advance in practical surgery we are chiefly indebted to the patient researches of our friends with the smock-frocks and the guinea-pigs. (5) Iodoform is of no peculiar value in the treatment of tuberculous lesions. The author has long since discarded it, and has not noticed any falling off in the results of his practice in consequence. Iodoform is an irritant and a poison; it is apt to be septic, as germs can grow upon it, but Mr. Owen said he had no knowledge of the truth of the statement that mushrooms have actually been cultivated on it. Other questions discussed are "the forcible straightening of carious spines" and "the treatment of vertebral caries."

Münchener medicinische Wochenschrift, Sept. 4, 1900.

Observations on the Cocainization of the Spinal Cord.—August Bier over a year ago published a paper (*Deutsche Zeitschr. f. Chir.*, April, 1899) in which the production of major anæsthesia by the injection of minute quantities of cocaine into the spinal canal was described and favorably commented on. At the same time the author drew attention to the very serious by-effects sometimes produced, and advised great care in conducting further experiments. His present communication is a protest against the recklessness with which the method is being applied, regardless of the fact that no noteworthy improvement in the technique has been made, and especially the dangerously large doses that are being employed. Experiments upon animals conducted under his direction have shown that like most drugs cocaine exerts a much more powerful and toxic action when thrown into the spinal canal than when administered by other avenues. As much as 4 cgm. have been used clinically at one injection, while in the author's opinion even 15 mgm. is a high dose and should not, and need not, be exceeded. In conducting further observations on the subject the point is not to apply the drug in the old way as originally described, which method is not very promising, but to attempt to devise means to reduce its toxicity when absorbed from the meninges, and to prevent the occurrence of unpleasant by-effects. Furthermore, the effort should be made to apply the method to operations on the entire trunk and the arms, and to find other harmless drugs which shall be also able to produce anæsthesia in this way.

A Peculiar Case of Azoöspermia.—F. A. Kehre, taking for his text the history of a case, urges the necessity for a more general recognition among the laity of the far-reaching results of gonorrhœal infection, which he considers almost entitled to rank with tuberculosis as a scourge of mankind. Before matrimony every individual who has suffered from a specific genito-urinary disease should submit his genitals and the testicular secretion to medical examination to determine their condition and especially the fecundating power of the semen. In the instance cited no spermatozoa were present in the semen of a man who had been married seven years before. Inasmuch as it was almost certain that the trouble dated back to a severe orchitis necessitating a unilateral castration, which was secondary to a gonorrhœal infection contracted thirteen years previously, the patient was told that his wife's statement that the two children she had borne were the offspring of another man was probably true.

A Case of Indirect Fracture of a Metatarsal Bone.—Ernst Maillefert says that while this form of injury is not infrequent in infantry soldiers it is rarely observed in civilians. The former usually acquire it on the march, when the feet are subjected to undue fatigue and when it is impossible to pay much attention to inequalities of the ground walked on, while these conditions do not obtain among other classes. The characteristic symptoms of fracture are usually absent, swelling and slight pain but no loss of function being commonly found, so that the true nature of the injury is usually overlooked, and inasmuch as displacement of the fragments is rare even *x*-ray examination does not reveal it. Cases of foot injury should always be most carefully tested for such a condition, and doubtless it would be found in many unsuspected instances. Rest in bed for from two to four weeks is sufficient in the way of treatment, as the broken bone is so well splinted by its neighbors that no dressing is necessary.

A Case of Intrauterine Compound Fracture of the Femur.—Otto Kraemer reports a case in which a pregnant woman in her fifth month, while attempting to raise a weight, experienced a severe pain in the abdomen. This gradually diminished, but did not completely cease until three weeks before delivery. At birth the child presented a sharp curvature in the lower third of the right thigh together with a healed cicatrix, undoubtedly the result of a healed intrauterine compound fracture.

The Diagnosis of Œsophageal Stenosis.—G. Holzknecht gives the details of a new method of applying the Roentgen rays to the diagnosis of œsophageal strictures. The introduction of a bougie filled with shot or mercury, and subsequent exposure of the patient to a protracted fluoroscopic observation under these conditions, is a disagreeable and sometimes dangerous procedure, the inconveniences of which the author's proposal is intended to obviate. Three tests are to be made; the first consists in causing the patient to drink several ounces of water holding gr. xv. to xxx. of subnitrate of bismuth in suspension as a shake mixture. If the stricture is of any degree of tightness a precipitation of the bismuth will take place at its site and be visible when properly illuminated. The only direction in which the œsophagus is accessible to observation is from the left behind, forward, and to the right, when it is visible as a light streak between the spinal column and heart shadows. In the second test the patient swallows a capsule containing the bismuth while the observer has the œsophagus under observation on the screen, the place of arrest of the black metallic shadow indicating the site of the stenosis. In corroboration of these two procedures, or in case they give a negative result, the deglutition of the capsule is preceded by the administration of a morsel of bread, which is sure to lodge in the stricture if present and arrest the test object in its descent. The advantage of this diagnostic measure is that it is applicable when the use of bougies is not permissible owing to suspected aortic aneurism, hæmatemesis, or the wishes of the patient, and that in a simple, safe, and painless way it gives accurate information concerning the presence, location, calibre, and length of a stricture.

The Chemical Resources of the Body Serving as Antidotes.—Alexander Ellinger understands under the term antidote used in this sense not alone the ability to render harmless a certain quantity of any poison which may have penetrated into the system, but the stopping of its toxic action after it has already reached the circulation. A consideration of the etiological investigations of recent years brings the conviction that a vastly greater proportion of diseases than is supposed is due to the action of poisons either directly introduced, produced by adventitious organisms which have gained access to the body, or originating within it as the result of anomalies of metabolism. The whole understanding of the processes by which the system is enabled to combat these substances is still shrouded in mystery, and the only direction in which it is possible to

approach the subject is by studying first the chemical processes by which the coarser poisons, whose composition is well understood, are disposed of. These are neutralization, oxidation, reduction, synthesis, and decomposition, but for the details of their application to specific reactions reference must be made to the original paper.

French Journals.

Nodules of Rabies and Rapid Diagnosis.—V. Babes refers to a previous publication in which he stated that if, after minute examination of the spine and bulb, no perivascular or pericellular miliary nodule was found, it was to be regarded as highly probable that the animal bitten was not mad. Pericellular nodules speak in favor of rabies. The nerve centres as well as the ganglia should be examined. When the bulb, marrow, and ganglia present no leucocytic thromboses or perivascular or pericellular undulations, we may suppose with great probability that the dog was not mad. If the dog died a natural death this examination permits us to exclude rabies with certitude.—*La Presse Médicale*, September 8, 1900.

Suppurative Arthritis Consecutive to a Penetrating Wound of the Knee Joint.—Xavier Delore gives a case with arthrotomy followed by recovery in a man aged sixty-three years. Suppurative arthritis of the knee after penetrating wounds presents such gravity, especially in the adult, that treatment should most often consist in resection of the knee. At any rate, in certain cases characterized by slow evolution and by attenuation of the virulence as shown by cultures and inoculations, arthrotomy is sufficient. It is justifiable by the results of laboratory research when the latter is possible. Benign arthritis of traumatic origin is an exception.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 9, 1900.

Abscess of Bones.—L. Longuet concludes an article in which he advocates trepanation by tunnelling as a substitute for trepanation by grooving or scooping out. There is nearly always absence of fluctuation. Distiuction must be made between tuberculous osteitis, syphilitic osteitis, chronic primary osteomyelitis, bony neoplasm, etc. Trephining is indicated in all bone abscesses. It is also imperative in neuralgic osteitis without tumor. The technique is indicated.—*Le Progrès Médical*, September 8, 1900.

The Practitioner, September, 1900.

Notes on a Case of Gastric Tetany.—J. Christian Simpson describes a case of tetany associated with dilatation of the stomach. Kussmaul was the first to associate tetany with gastrectasis in 1869, and latterly it has been observed more particularly—ninety-two per cent. according to Fenwick—in those who have pyloric or duodenal disease rather than a primary affection of other parts of the stomach. Its mortality has been placed as high as seventy-five per cent. As to treatment, if the active cause be auto-intoxication, this must be dealt with in two direct ways; first, to remove the gastric and, if possible, the intestinal contents; and secondly, to flush the toxins out of the blood and lymph by saline transfusion in one way or another. A secondary point in favor of the saline treatment is the relief it gives to thirst. After the acute symptoms have been alleviated comes the question of operation as a preventive of further attacks, by curing or relieving the local gastric condition which allows the auto-intoxication to be carried on.

The Surgical Treatment of Trigeminal Neuralgia.—Victor Horsley has in twenty-one cases removed the Gasserian ganglion for the cure of trigeminal neuralgia, limiting this term strictly to what was originally called tic douloureux. In the early stages the disease can be treated by drugs, but neither drugs nor electricity bring about a cure. All clinical evidence seems to point to the fact that it begins in the peripheral branches of the fifth nerve, and creeps as an inflammatory process up the peripheral branches of the nerve until it reaches the Gasserian ganglion. The writer describes the technique of the operation, and says that out of the twenty-one cases operated on there were only two deaths. He has operated on four patients over eighty years of age, so that age itself is not necessarily a bar to the operation. In no one of his cases has he seen a recurrence, and his experience extends over five years.

Some Disorders of Memory Associated with Epilepsy, with Special Reference to "Reminiscences."—H. Campbell Thomson describes a reminiscence as a strange, evanescent feeling of familiarity with some place or event which occasionally crosses the mind, although the place is being visited or the event happening for the first time. They occur in otherwise healthy people, but their occurrence must be looked upon as abnormal, and probably due to a localized discharge of nervous energy. Undue or sudden increase in the frequency or intensity of sensations should be viewed with suspicion, and should lead to careful inquiry for any other suspicious symptoms. Their association with any other slight symptoms of epilepsy, which may be so trivial as almost to pass unnoticed by the patient, is of the utmost importance, and will often permit an accurate diagnosis to be made and early treatment to be adopted.

A Clinical Lecture on Pelvic Pain.—By G. Drummond Robinson.

The Edinburgh Medical Journal, September, 1900.

Sarcoma of the Suprarenal Capsules in a Child Aged Seven Weeks.—John Orr reports a case which presents the following points of interest: (1) The extreme youth of the patient. Abdominal swelling had been noticed as early as five weeks. (2) The entire absence of any symptoms pointing to the organ affected. One would have expected involvement of or pressure on the kidney, but evidence of such never occurred. (3) The absence of all bronzing, or cutaneous or mucous pigmentation of any sort, which seems to be a point of distinction between malignant disease of the suprarenal capsules and tuberculous affections of these organs associated with Addison's disease. (4) The peculiarly smooth, uniform character of a secondary hepatic enlargement, especially the deceptive and misleading enlargement of the left lobe, which was erroneously supposed during life to be the spleen.

L'Union Médicale du Canada, August, 1900.

Voluminous Chondroma of the Leg in a Patient with Cutaneous Angioma.—A. Marien reports the case of a young girl aged fourteen years, whose leg was amputated because of a large tumor which from its macroscopic and clinical characters was supposed to be an osteo-sarcoma. Microscopic examination showed it to be a chondroma. It first appeared when the child was only four years old, and followed a severe injury caused by a fall. For about eight years it was quiescent, very slightly painful, hard, smooth, and the size of a hen's egg. It then began to grow, and invaded the whole circumference of the leg, attaining the size of a child's head. For a year and a half previous to the operation the patient was unable to walk, the slightest motion of extension causing exquisite agony. Angiomata were found on the lower left eyelid and the dorsal surface of the left foot. This would seem to point to some congenital affection.

Attempt at Murder.—J. O. Villeneuve reports in detail the case of a boy aged fifteen years, who attempted to kill a station-master whom he saw handling a large sum of money. The boy acknowledged the crime and regretted it, attributing it to a momentary evil impulse. He was intelligent, but had been early deprived of home influences and obliged to work for masters who overtaxed him and, in most cases, cheated him out of his wages. The question arose as to his mental condition, and responsibility for the act. He was found guilty, but recommended to mercy, and sentenced to five years in a reformatory school.

Two Cases of Cysts with Torsion of the Pedicle.—L. Harwood describes two cases of ovarian cysts which were removed by operation, the patients making a good recovery.

Chemical Analysis of Potable Water from a Hygienic Standpoint.—By J. A. Chopin.

Finska Läkaresällskapets Handlingar, July and August, 1900.

Dietetic Treatment after Gastrotomy.—Max Buch observes that very frequently in the case of patients who have had a gastrotomy for atresia of the œsophagus, improvement does not follow in spite of nourishment introduced into the stomach. The reason for this appears to be that when food is introduced directly into the stomach, the secretion caused by stimulation of the pneumogastric nerve by appetite and the pleasure of the palate is absent, and digestion incomplete. Pancreatic secretion, which is usually in proportion to the gastric juice, is also deficient, and there is of course no salivary digestion. The patients should be made to masticate their food, and be given palatable food, and anything repugnant to their taste should be avoided. Bouillon, water, and milk have slight influence on the psychically induced secretion, but they have on the reflexly induced secretion, and can therefore be introduced directly into the stomach. Solids, especially starchy foods, should be masticated because the psychically induced gastric juice is more potent upon them than the juice produced by reflex action on the sympathetic.

The Treatment of Rupture of the Uterus.—Georg von Zweygberg gives the statistics in regard to twenty-six cases treated in the Helsingfors Hospital since its foundation in 1833. Only two of the mothers and none of the children lived. In twenty-two cases treatment was conservative; in four operation was performed. The death of twenty-one patients who were treated conservatively was due in eight cases to septicæmia with peritonitis, one

and one-half to eight days post partum; six times one-half to twenty-two hours post partum with signs of peritonitis; once probably from septicæmia with pelvic abscess, twenty days post partum; three times from profuse hemorrhage one and one-half to three or six hours after labor; once immediately after delivery (the patient was dying when admitted); twice two to three days after labor, cause not recorded. In the cases operated upon, death was due to septicæmia. The high death rate is doubtless owing to infection during labor.

Arteriosclerosis: its Clinical Aspect, Symptoms, Course, and Treatment.—J. W. Runeberg says that the heart is the chief organ affected by this disease. He divides the disorders caused by arteriosclerosis into three chief classes: (1) Syphilitic sclerosis, attacking the large and medium-sized arteries, characterized by intense local symptoms, without general circulatory disorders; (2) sclerosis of the type of granular atrophy (arterio-capillary fibrosis), a general affection of the small arteries and capillaries, characterized by slight local symptoms, but by serious general circulatory disturbances; (3) the sclerosis of old age, a general affection of the large and medium-sized arteries, characterized by mixed symptoms of the various organs and disorders of the general circulation. These three varieties may be found combined.

Retrosternal Goitre with Grave Dyspnœa.—E. Sandelin reports a case of severe dyspnœa due to a retrosternal goitre. Tracheotomy gave only temporary relief, for which reason strumatomy was performed, and complete recovery ensued. The tumor was a benign colloid goitre, which had developed in the left lobe of the thyroid gland. In its lower posterior portion was an extravasation, to which the author attributes the dyspnœa. The larynx and the upper part of the trachea were pushed to the right and bent, and the walls of the trachea were flattened; lower down, behind the sternum, the tumor had completely flattened the trachea. From the fact that these deformities persisted after removal of the tumor, it may be supposed that they had existed for a considerable time.

Myxœdema in Childhood.—Albert de la Chapelle reports a case in a girl aged fourteen and one-half years, who since the age of two years has had symptoms of the disease, with almost complete arrest of physical and mental development. Under thyroid treatment, continued for four years, the symptoms of myxœdema have disappeared, the body is less deformed, and the movements are more active. She has grown twelve inches, the large fontanelle has ossified, and the patient has twenty-eight new teeth. The genital organs have not developed, nor has puberty appeared. The patient has improved mentally to the extent that she can attend to her own needs and no longer has a mania for destroying and picking up objects.

Speech in Memory of J. M. Charcot at the Banquet of the Neurological Society at Paris, August 9, 1900.—By E. A. Homén.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE PLAGUE IN GLASGOW—COMMISSION ON DYSENTERY AND TYPHOID—WAR HOSPITALS COMMISSION—BRITISH ASSOCIATION'S MEETING—PRIVATE ASYLUMS—THE LAMENT OF THE DEALERS IN POISONS.

LONDON, September 7, 1900.

THE outbreak of plague at Glasgow is a source of some alarm and much speculation throughout the country. After I sent off my last letter some other cases occurred, and the next day there were eleven in hospital and ninety-three contacts isolated. You will have learned by cable the daily numbers. We heard on Monday that your sanitary authorities had imposed quarantine, and of course other places are doing the same. Our port authorities are pretty confident of their ability to meet the danger, and you know a few years ago they kept cholera out of London. On Tuesday there were fourteen patients in hospital, three doubtful, and one hundred and three persons isolated. On Wednesday the hospital cases stood at thirteen, one doubtful. Yesterday the figures were the same, and one hundred and nine persons are still under observation. All the patients are progressing satisfactorily, and the authorities are confident of their ability to restrict the outbreak. The health committee will keep all contacts isolated until the houses from which they have been removed have been thoroughly cleansed and disinfected. They are also ready to accept any "suspects" from any suburb. In some districts a "scare" has taken place for a day or two, but generally a calm confidence prevails. In Govan the same precautions are taken, and the single case has not been followed by another.

The commission to "inquire into the nature, causation, pathology, and modes of prevention (more particularly as affecting armies in the field) of dysentery, and its connection, if any, with enteric fever," consists of Prof. W. J. R. Simpson, J. Lane Notter, and Major D. Bruce, R.A.M.C. On accepting this office Colonel Notter has resigned his professorship at Netley and is succeeded by Major Frith. It is hoped that this commission will obtain valuable information.

Items of evidence before the War Hospitals Commission continue to attract some attention even on the part of those who are determined to await the conclusion of the inquiry before attempting to digest them or to form an opinion on the questions involved. Thus one officer admitted that a portion of some stores was mislaid for three days and another part delayed at the base. Major Watson said Indian ambulances were superior. Colonel Exham, principal medical officer, declared that on his arrival on April 23d at Bloemfontein there was ample accommodation, and to meet the rush after the advance he added to it largely. He flatly contradicted several statements of Mr. Burdett-Coutts, and denied that there were ten thousand patients on May 22d, the highest number on any day being four thousand and ninety-eight men and one hundred and seventy-eight officers, and there was no insufficiency of staff. Nor was there any foundation for Mr. Burdett-Coutts' statement that convalescents were sent down without proper food. He put in a statement controverting in detail Mr. Burdett-Coutts' allegations, and said he believed the sanitary arrangements at Bloemfontein were satisfactory and not accountable for the outbreak of fever. Further, he was not aware of any friction between the military and civil surgeons at No. 8 hospital. On this last point, however, other witnesses spoke of the existence of some friction. Dr. Kirkman declared every necessary was deficient, and specified bed-pans, feeding-cups, and utensils. Dr. Whittington corroborated him. Dr. Fitchell said some of the orderlies had been drunk, and he thought the senior officers were indifferent to the state of the patients, though he had seen the principal medical officer inspecting the tents. Dr. Leon, in charge of the enteric division, said there was a shortage of utensils, and requisitions for them and for more orderlies and nurses took a fortnight to be complied with. Colonel Butcher attributed the delay to the exigencies of railway transport. He was never short of blankets, there was an ample supply of all articles except bed-pans, bedding, and mattresses; the shortage lasted five weeks and was due to interruption of transport and the excessive number of patients. Dr. Johnstone, who practised for years at Bloemfontein, said there was typhoid among the Boers at several places, and they took it with them to Paardeberg, where the British of course contracted it. He thought the principal medical officer was too sparing in bedding.

The British Association for the Advancement of Science held its annual meeting on Wednesday at Bradford, where it was cordially welcomed. The president this year is Sir William Turner, who is quite at home in such a position. His opening address was devoted to a careful review of the century's progress in the department of science he so well represents and adorns. The advance of knowledge of animal structures, especially in reference to the cell theory, was an attractive subject and interested the large audience. The sections were opened on Thursday, most of them by addresses of their presidents.

Private asylums have been a good deal to the front lately, and much ink has been shed by correspondents who are not well versed in the differences of the law relating to the different classes of lunatics. Undoubtedly there are extra precautions in the law for the protection of private patients, but that is because in their cases the motive for consigning them to an asylum is more open to suspicion. No one is likely to take a pauper to a private asylum and pay heavy expenses for his accommodation. Then the keepers of such asylums are bound to forward to the commissioners every letter of a patient, and that unopened. The possibility of a lawsuit must also be present continually to the minds of such owners, for litigation would probably spell ruin, and border cases must be a source of great anxiety.

The dealers in disinfectants are making a great outcry against the order adding carbolic acid to the poison schedule. They now say nearly all disinfectants contain this poison—a fact they grievously tried to conceal. They plead for the poor, who could hitherto buy two pennyworth at the grocer's, but will now have to go to the chemist and have it registered and labelled. "Pity the poor" is an excellent cry, but here it seems to mean pity the tradesman, and let the poor supply the holocaust of accidental poisoning. It is surprising that the manufacturers of poisons should have the impudence to father such a plea for their profits.

POSITION IN LABOR.

To the Editor of the Medical Record.

Sir: Some twenty-five years since the New York Medical Record published a letter from me entitled "Position in Labor." I was called to attend our pastor's wife in labor, over thirty-two years ago. For several hours she made no progress—what was the trouble? Easier asked than answered. The question arose, had position anything to do with the lack of progress? I questioned the lady as to the position she occupied when lying in bed. Her reply was that she "had usually lain upon the right side." I had her at once assume a position on that side, and to my gratification her labor took on a favorable and satisfactory turn. The child was soon delivered.

Many times after that I had women in tardy labor change their position to that occupied for some weeks prior to confinement, with like results; and I became convinced that there was a good deal in this question of position. I called the attention of several medical men to this subject, who told me of their experience. There is a good deal in this question of position.

But again, some thirty years since I was called to attend a young lady in her first labor. The forceps was used in her mother's labors, she warned me, and I would have to use the forceps in her case, and did so successfully. I used the forceps in other labors of this woman. When I was called on another occasion, this lady remarked to me, "You will have to use the instruments." My reply was, "I will see." I had used the knee position a good deal in difficult labors with satisfactory results, and resolved to use that position in this case. She was placed on a cushion on the floor, with a person in front for support. The result was that an infant was delivered in a short time. I attended this woman once, and I think twice, afterward with like results. I attended her sister-in-law a number of times. The first child was still-born—this was in September, 1881. In most of her confinements I had to use the forceps. In one case her husband, a strong man, took hold of the forceps with me, and straightened out one blade of Bedford's forceps. Finally, I resolved to try the knee position in her next case, and did so in two subsequent labors with satisfactory results.

My experience has been such, in the more than forty-seven years since I received my degree of M.D. in New York City, that I have come to consider the knee position to be the normal position in the very many difficult labors, and I believe that the assumption of this position will obviate the necessity of instrumental labors in very many cases.

For several years I have thought to write this experience out, believing the matter of so much importance.

A word further upon the use of chloroform. Some thirty-five years ago I had a case of labor in which there were convulsive symptoms. I used chloroform at once, which relieved those symptoms, and since that time I have used chloroform when the pains were severe. My mode of using it was to have the patient inhale the chloroform while the pain was on, and only then.

S. Haynes, M.D.

Saranac, N. Y.

DEFENCE OF SUITS FOR ALLEGED MALPRACTICE.

To the Editor of the Medical Record.

Sir: I was very much interested in the editorial which appeared in your journal for September 15th, entitled "Plea for a Medical Defence Union in the United States," and which was based on an article that appeared in the *St. Paul Medical Journal* for July, written by Dr. Donald B. Prichard, in which you state as follows: "His idea is to organize a mutual association, the membership of which should be confined to those who belong to the State or some properly organized medical society. In order that the organization might be of the highest standing, it would not be proper to defend one guilty of gross malpractice. That this might be accomplished, every case should be submitted to a standing committee, who after a thorough examination would decide whether or not it would be proper for the association to defend."

The New York State Medical Association, last winter, believing that the time had come when State organizations of physicians must do something more for their members than simply to furnish a scientific meeting once a year, if they would keep abreast of the time in which we live, applied for a charter from the legislature (which was granted) giving it increased powers, especially in regard to its legal rights, as shown in Section 2: "'The New York State Medical Association' may and shall have perpetual succession, shall be capable of suing and being sued, of pleading and being impleaded, answering and being answered unto, defending and being defended, in all courts and in all causes whatsoever."

In the by-laws, which the committee on reorganization has drawn up in conformity with this charter, the following provision is made for the protection of its members from suits for alleged malpractice. Section 6, Article 2: "It shall be the duty of the council to receive and consider all applications of members of 'The New York State Medical Association' for assistance in defence of suits for alleged malpractice, or other matters affecting their professional status, and all complaints of violations of the laws of medical practice and of public health; and the council shall without delay, and with the advice of its attorney, examine the case and determine the expediency of defending such action or prosecuting the alleged violators. . . . If the council's decision be in the affirmative, then the 'New York State Medical Association' shall furnish the funds and legal services necessary for the conduct of such defence or prosecution."

From this you will readily see that it is our intention to defend only such of our members as can show that they have been reasonably right in their treatment of their patients. We believe that much benefit will accrue to the general profession as well as to the individual practitioner from State organizations looking out for the welfare of each of its members in any matter relating to their professional honor and status. Common interests are necessary if we desire to bind men together into a compact and strong organization, and we believe that this can best be done by the concentration of all work which can be done by medical men in these county, State, and national associations in addition to the ordinary scientific work which these associations are in the habit of doing.

The multiplication of associations having different objects in view weakens the profession by subdividing the interests of its members.

Frederick Holme Wiggin, M.D.,
Chairman Committee on Reorganization, New York State Medical Association.

Reviews and Notices.

A Dictionary of Medicine and the Allied Sciences. Comprising the Pronunciation, Derivation, and Full Explanation of Medical, Pharmaceutical, Dental, and Veterinary Terms, together with much Collateral Descriptive Matter, Numerous Tables, etc. By Alexander Duane, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute; Reviser of Medical Terms for Webster's International Dictionary. Third edition, enlarged and thoroughly revised. Philadelphia and New York: Lea Brothers & Co. 1900.

An epidemic of dictionary making passed over the medical profession a few years ago, and some eight or ten works, some in several volumes, others in a single volume of unwieldy bulk, others again of pocket size, were successively brought out for the convenience and instruction of students and practitioners. Some of these have already disappeared from view, and some others ought to follow them. Among those which have survived the test of actual use and have appeared in successive editions, one of the most deserving is that of Dr. Duane. The book is of convenient size to be taken from the shelf by others than Sandow, yet is large enough to contain all the words that any reader of medical literature is likely ever to come across. The type is small but clear, the definitions are correct so far as our examination has gone, and the tables are good; but the figured pronunciation is in many places execrable. In most cases this attempt to represent the sounds is of benefit only to a foreigner, and he often pronounces badly enough without being misled by an assumed authority, as he assuredly would be if he consulted this dictionary. It is to be hoped, if this work reaches a fourth edition, as we trust it will, that the author will cut out this useless feature. It is a pity to mar a book of such excellence as is Duane's dictionary.

A Manual of Personal Hygiene. Edited by Walter L. Pyle, A.M., M.D., Assistant Surgeon to Wills' Eye Hospital, Philadelphia; Fellow of the American Academy of Medicine; Former Editor of the International Medical Magazine. Philadelphia: W. B. Saunders & Company. 1900.

This is apparently primarily intended to be a work for the guidance of the laity, but we fear there are many members of the medical profession whose knowledge, or at least practice, of the elementary rules of hygiene is so slight that they are in as great need of direction as their patients. There are seven writers of this work, each contributing a

chapter, as follows: Hygiene of the digestive apparatus, by C. G. Stockton; of the skin and its appendages, by G. H. Fox; of the vocal and respiratory apparatus, by E. F. Ingals; of the ear, by B. A. Randall; of the eye, by W. L. Pyle; of the brain and nervous system, by J. W. Courtney; and physical exercise, by G. N. Stewart. There is a sufficiently complete index, but one should read the book through first, and use the index only when he subsequently wishes to refresh his memory regarding some special point. We can commend the book as sound in advice and as free from the common fault of books for the laity, of going too deeply into purely medical and technical matters.

Dermato-histologische Technik. Von Dr. Max Joseph und Dr. George Loewenbach. Second edition. Berlin: Louis Marcus. 1900.

This guide to histology of the skin, especially prepared to demonstrate the technique to students and physicians, has reached its second edition within a brief period, and has been enlarged and improved, meeting the requirements in an excellent manner.

Report on the Mortality Records of the Mutual Life Insurance Company of New York, for Fifty-six Years, from 1843 to 1898. By Elias J. Marsh, M.D., and Granville M. White, M.D., Medical Directors. New York: The Mutual Life Insurance Company. 1900.

This collection of tables is of great value to the medical statistician as well as to the insurance man. The very careful analysis of the tables made by Drs. Marsh and White is exceedingly interesting to the plain medical man who is neither a statistician nor an insurance examiner, but who is curious as to the relation of age to the several diseases of greatest fatality.

The Medical Directory of New York, New Jersey, and Connecticut. Published by the New York State Medical Association. Vol. II. 1900.

This is an almost indispensable work for the physician in this city or State, who cares to know anything of his colleagues and of the work in which they are engaged. We are glad to note several improvements in this volume, especially in the list of hospitals, where we find information as to the class of patients admitted, the names of the consulting, attending, and house staffs, and such other matters as may be of value. Other useful features of the volume are an official list of registered pharmacists, and a list of the health board stations in this city at which antitoxin and culture outfits may be obtained.

Manual of the Diseases of the Eye, for Students and General Practitioners. By Charles H. May, M.D., Chief of Clinic and Instructor in Ophthalmology, Eye Department College of Physicians and Surgeons, Medical Department Columbia University, New York. New York: William Wood & Company. 1900.

We know of no book at present before the profession which better answers its purpose than this. It is not intended for the specialist, but for the student, who needs an elementary knowledge of ophthalmology as of the other specialties to fit him for graduation, and for the general practitioner practising at a distance from cities where specialists congregate, who is obliged to treat many cases of eye disease whether he will or no. Such a one will find here, expressed in clear and not too ophthalmologically technical language, just the guide he needs to enable him to benefit his patient and save his own reputation. The book will also teach him to recognize the serious eye troubles which he had better not attempt to treat.

Beneath Hawaiian Palms and Stars. By E. S. Goodhue, M.D., Government Physician; Medical Superintendent, Malulani Government Hospital, etc. Illustrated by photographs and pen sketches. Cincinnati: The Editor Publishing Company. 1900.

This is an entertaining description, made after no particular system or order, of matters in the Hawaiian Islands. The author writes in a colloquial and rambling style that is a little provoking at times, for just as the reader becomes interested in some description he gets a jar by being shunted off on some other subject; then probably the writer forgets to come back and pick up the thread he dropped, and the reader is left with his curiosity piqued but unsatisfied. However, there is enough information in the book on all imaginable topics, from coffee to leprosy and from missionaries to annexation, to satisfy any one, and though descriptions of what we learned at school to call the Sandwich Islands are plentiful we have read none that gives more practical information than this. Dr. Goodhue has lived several years in the islands, and his book is filled with the knowledge he has himself acquired, and not that gathered at hearsay during a hurried visit to Honolulu. It is well worth reading despite its peculiarities of style.

Transactions of the American Association of Obstetricians and Gynæcologists. Vol. XII. For the year 1899. Philadelphia: William J. Doran. 1900.

This volume contains the usual number of papers, good, bad, and indifferent, but chiefly good. Some are illustrated with plates and wood-cuts in the text.

Transactions of the Southern Surgical and Gynæcological Association. Vol. XII. Twelfth Session, held at New Orleans, La., December 5, 6, and 7, 1899. Published by the Association. 1900.

This is one of the most active and progressive of the special societies in the country, and its volume of transactions always contains many papers of interest. The present volume offers no exception to this statement.

Les Tubercules des Pédoncules Cérébraux. Par le Dr. Georges Edouard Raviart, Ancien Interne des Hôpitaux de Lille, etc. Paris: Georges Carré et C. Naud. 1900.

This interesting monograph, based upon the study by the author of a case of tubercles of the cerebral peduncles, contains a résumé of all the cases of this condition of which the writer has been able to find reports in medical literature, forty-three in number. The morbid anatomy, symptomatology, and diagnosis of this rare affection are quite fully discussed, and we may say that Dr. Raviart's work contains an epitome of all that is known at present of these neoplasms. A bibliography of one hundred and seventy-one titles is appended.

A Text-Book of Practical Therapeutics. With Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by Drs. G. E. de Schweinitz, Edward Martin, and Barton C. Hirst. New (eighth) edition. Philadelphia and New York: Lea Brothers & Co. 1900.

It is hardly necessary to review a book which is so well known as this, and the popularity of which is evidenced by the fact of eight editions in ten years. It differs from many works of the kind, and herein probably lies the secret of its popularity, in that the author does not take it for granted that his reader already knows the subject perfectly. He addresses himself to students and endeavors to teach them what they ought to know in order to become reasoning physicians. The drugs—their source, preparations, physiological actions, and therapeutic uses, are treated of in alphabetical order, no attempt at classification having been made. Although especially adpated to the needs of the undergraduate student, the book will be found to be a useful work of reference by the practitioner who may be temporarily in doubt or difficulty.

A City Hall and Basement Schools.—Major Farley is right when he says that no money should be spent upon a new city hall for Cleveland so long as one child remains in a basement school. The educational, utilitarian, and æsthetic value of fine buildings in a city is not to be questioned; but it sinks into unimportance when compared with the city's crime in forcing a large number of its children to attend school in poorly lighted and worse ventilated basements. We hope the committee of the Cleveland Medical Society appointed to study the school question will be able to suggest practical ways and means for permanently and radically improving the unhygienic conditions under which our school children are condemned to work. It has been said that the basement school-room is even at its worst a more hygienic place than the homes from which many of the children come who occupy it, but this is really an additional reason for improving the school conditions. . . . This question of basement schools has much to do with the sobriety, industry, and health of the coming generations, and in comparison five or ten years' delay in securing a magnificent city hall is a mere bagatelle.—*Cleveland Medical Journal.*

Society Reports.

CANADIAN MEDICAL ASSOCIATION.

Thirty-third Annual (Century) Meeting, Held in the Academic Hall of the Ottawa University, Ottawa, on September 12, 13, and 14, 1900.

Dr. R. W. Powell, President, in the Chair.

The minutes of the last meeting, held in Toronto, were read by the secretary, Dr. F. N. C. Starr, of Toronto, and adopted.

Dr. Drewer, of Ottawa, presented the report of the committee of arrangements.

The Present Status of the Eliminative and Antiseptic Treatment of Typhoid Fever.—Dr. W. B. Thistle, of Toronto University, read this paper. Some seven years ago he had introduced this plan of treatment of typhoid fever to the profession. He claimed that this form of treatment for typhoid fever had time and again been misrepresented by Professor Osler and others, as he had never held to the opinion that the eliminative and antiseptic plan could rid such organs as the liver and spleen of the bacilli lodged in them. When once the typhoid bacilli gained access to the intestinal tract, the multiplication of them occurred with extreme rapidity and the intestinal contents teemed with countless numbers of them. These were not confined to the intestine, but were to be found in the walls and in fact in almost every organ of the body. He was of the opinion that the draining of the intestinal walls following upon the action of a purgative, either calomel or magnesium sulphate, would tend to get rid of some of these bacilli in the intestinal walls, but he did not claim that it would effect their exit from the liver, etc. He thought the treatment had been imperfectly applied in many instances without a clear conception of the underlying principles. Under this plan of treatment Dr. Thistle had never had a single case of hemorrhage, what hemorrhage occurred having been always very slight. He had also had very few perforations, and twenty per cent. of the death rate was from perforation and hemorrhage. In Toronto this plan of treatment was universally adopted. Statistics at the Toronto General Hospital showed that from 1893 up to the present time there had been eight hundred and thirty-three cases in that institution, with fifty-six deaths—a mortality of 6⅛ per cent.

Dr. McPhedran said that he had been watching Dr. Thistle's work in this direction from the time of the appearance of his first paper on the subject, but could not agree with all his conclusions. He did not think that this plan of treatment lessened diarrhœa, tympanites, fever, or delirium. He considered that Dr. Thistle was harboring the idea that purgatives in typhoid were a new discovery with him; this was not so. Twenty-five years ago the speaker gave these for the first ten days at least. In addition to this he used to give carbolic acid and iodine, and in a certain class of cases he thought he had the exact treatment. Another class would then come along in which that treatment had no effect whatever. He considered that the general toxæmia that existed could not be eliminated through the bowel; it had to be done through the kidneys and skin.

Dr. Thistle, in his reply, emphasized the fact that he was not trying to eliminate bacilli from the glands; in clearing out the bowels he was trying to eliminate toxins from the body and not bacilli.

A Case of Sarcoma of the Right Nasal Fossa with Acute Sinusitis and Orbital Cellulitis. — Dr. Perry G. Goldsmith, of Belleville, Ontario, presented this paper and patient. The patient was a man aged thirty-eight years, a farmer, with an unimportant family and personal history. He consulted the doctor on August 4th last, with severe frontal headache and double vision. Examination of the nasal fossæ revealed growths which along with some of the bone in the right fossa were removed. After this swelling and pain in the eye began, so that it was seen to project far forward, downward, and outward. The right nasal fossa was curetted, the tissues being sent to Professor Anderson, of the Trinity pathological laboratory at Toronto, who pronounced them of sarcomatous origin, small round-cell variety, with the walls of the blood-vessels thin and poorly developed. The discharge from the nostril was of an odor similar to that emanating from cancer of the rectum. Up to ten years ago Bosworth had collected forty of these cases.

Dr. R. A. Reeve stated that a number of years ago he had presented a paper before this association on the same subject. He directed attention to the importance of examining the naso-pharynx in diseases of the orbit. He instanced a similar case to Dr. Goldsmith's. In his case there was little pain, but an examination of the nose revealed the tumor.

Some of My Experiences in the South African War.—Dr. George S. Ryerson addressed the association on this subject. He dealt first with the experience gained of modern bullets. The very latest returns showed that 986 officers and 11,701 non-commissioned officers and men had been wounded, of whom only 732 died of wounds received in battle, which was to be ascribed to the aseptic character of the bullet and the prompt attention and antiseptic treatment. Dr. Ryerson then dealt with the wounds caused by these bullets. Referring to poisoned bullets being used, he said this was not the truth, as the tarnish or verdigris probably accumulated in transit through the barrel. He also doubted the fact of explosive bullets being used. The Boers made use of thousands of the Martini-Henry, a heavy bullet, which caused great destruction of soft parts, necessitating amputation. There were few amputations in this war. He quoted Kendal Franks, who had performed twenty amputations in two thousand cases. While abdominal section in wounds of the abdomen was mainly inadvisable, he saw one case in which the results were excellent. He spoke highly of the magnificent work of the Royal Army Medical Corps.

Dr. T. G. Roddick, M.P., told of the great sacrifices of Dr. Ryerson in proceeding to South Africa at his own expense to carry out the work of the Red Cross Association. While in England recently, he stated he had made it his special business to inquire of returning Canadian soldiers as to the hospital management in South Africa, and although he had spoken to many of these, he had completely failed to find a single Canadian who had anything but praise for the hospital arrangements in that country.

Our Race and Consumption.—This was the title of a very able paper contributed by Sir James Grant, of Ottawa, who considered it an important fact and one worthy of consideration that races had been born on this continent, had lived and entirely disappeared, leaving mounds in the West and other traces in Florida and elsewhere of their undoubted existence; and that thus far there was no information as to the exact cause of the disappearance of these races. He thought it remained for the Anglo-Saxons to see whether they would prove more successful than their predecessors in establishing themselves on this continent. He referred to the loss of three thousand lives in the fair province of Ontario in 1898 by consumption alone, and deplored the fact that the people were not as yet alive to their danger. Sir James indorsed the legislation passed at the last session of the provincial Parliament designed for the purpose of assisting

municipalities in the erection and maintenance of sanatoria for consumptives.

Recognition and Management of Tabes Dorsalis.—Dr. Allan McLane Hamilton had prepared this paper, but on account of illness was unable to be present to read it. The president undertook this task. It appeared that, as an etiological factor, syphilis was not referred to by the early writers on this disease. While some would attempt to divide the symptoms of the disease into the leg and eye types, the writer would consider that to be unwarranted. He considered there was a close resemblance or rather relationship between the different forms of cerebro-spinal sclerosis. There was no disease of the nervous system which had drawn forth so many plans of treatment; and but little or no good had resulted from any one thing. Most tabetics were favorable subjects for expectant treatment, and many derived temporary benefit from some new drug. Looking back over a number of years, he found that most good had been accomplished when little or no medicine had been given. He had found rest by suspension and persistent cauterization of the back good treatment. In the opinion of the writer, syphilis could not be traced in more than fifty per cent. of the cases. For the arthropathies there was little to be done. Perforating ulcer was a rare feature of locomotor ataxia, and most obstinately resisted treatment. He had seen three cases of this unusual condition in ataxics, and the ulcer rarely exceeded 2 or 3 cm. in diameter. One authority mentioned five cases resulting in cure by means of nerve stretching. Throughout the course of the paper numerous cases were cited with their symptoms and treatment.

The Physician's "Vaster Empire."—In this paper Dr. John Hunter, of Toronto, dealt with the questions of sanitary science, education, social purity, and medical missions. Referring to sanitary science, he entered a plea for the broader and freer application of the principles of this branch of medicine, in the building and construction of our homes, schools, churches, theatres, etc. No dwelling-house should be constructed except under the supervision of an architect and a physician versed in sanitary science. In the matter of sanitary science architects had improved wonderfully during the past ten years. Another important question was that of our educational system—the mental and physical health and development of our school children. The best way to secure physical vigor and high mentality was surely within the province of the physician to grapple with and study. In all forms of social purity and impurity, physicians should speak *ex cathedra* against every form of vice and immorality. The boys and the girls of the family should be enlightened as to their sexual proclivities at proper periods, by their fathers and mothers respectively. In medical missions he referred to the vast field for medical missionary work in foreign countries.

Address in Surgery—Tuberculous Lesions from a Clinical Point of View.—The president introduced Mr. Edmund Owen in a few well-chosen words. This address was delivered at the evening session of the first day, and the distinguished visitor was greeted by a crowded house. In commencing his masterly address, he stated that he would deal with tuberculous lesions as the surgeon met them day by day in the hospital wards, in private practice, or in the operating-theatre. Referring to the pathologists, he considered his (the pathologist's) thought to be only of the dead tissue, while the surgeon saw the human tree during its life and rarely followed it after death. The student did clinical and pathological work at different times; and he was enabled to follow the case straight from the ward to the laboratory. He considered that study of the fresh specimen was the best; for the specimen taken from formalin was no more like the actual condition than canned salmon was like fresh-run fish. He would not hinder experimental research work; it was absolutely necessary. The life of a man was of more value than a sparrow or many guinea-pigs. It would be almost impossible to overestimate the direct value of experimental laboratory work. Strumous and scrofulous were now terms devoid of meaning, and tubercle was now called by its proper name. There were three great factors in connection with tuberculosis which the public must be made acquainted with: (1) The disease was communicable; but the public must be allowed a little time before accepting this statement and fact. (2) The disease was preventable; this followed almost as a corollary to the first statement. (3) The disease was curable. Years ago the subject of tuberculosis was regarded as wellnigh hopeless; but now it was not considered of the untractable nature that it was formerly thought to be. Tuberculous lesions were exactly what they used to be; and Mr. Owen had worked at the largest children's hospital in London for over a quarter of a century. We now took a much more hopeful view of these lesions. Many of his hearers had studied tuberculous lesions under these skies and also in the mother country. Did they find that the tuberculous lesions were the same in both hemispheres? One rarely heard now of the vis medicatrix naturæ; surgery had rendered it superfluous. All had noticed cases of old standing hip-joint disease in which in time the sufferer actually grew out of his trouble. This might be a popular superstition, but, like most erratic beliefs, it was founded upon a stratum of truth. In children these chronic diseases were always tuberculous. When chronic abscesses occurred, it would not do to open and drain, but they must be scraped out—their unhealthy lining destroyed. In the treatment of these diseases, the speaker stated that he had failed to find any virtue whatever in the employment of iodoform. It was an irritant and a poison, and it was apt to be septic, as germs can grow on it. Mr. Owen condemned the use of complicated apparatus, and also forcible correction in cases of spinal deformities. He considered that this deformity did not lend itself to operative treatment. There might perhaps be a small class of cases in which it might eventually be found applicable, as when bone or organized inflammatory deposits pressed upon the cord so that the patient had lost movement in the lower extremities. The plaster-of-Paris jacket must be held responsible for much of the deformity of Pott's disease. The proper treatment of these cases was rest in the horizontal position, with plenty of good fresh air and sunlight.

At the conclusion of his extremely able and instructive address the thanks of the association were moved in a complimentary speech by Professor Shepherd, of Montreal, and seconded by Professor Cameron, of Toronto, put by the president, unanimously carried amid great enthusiasm, and appropriately presented to Mr. Owen by Dr. Powell. Mr. Owen made a happy reply.

Excision of the Knee Joint in Tuberculous Disease.—Professor Primrose, of Toronto University, minutely described Kocher's method of dealing with tuberculous disease of the knee joint. He recited the histories of a few cases in which he had obtained excellent results, in which this operation had been employed. The steps of the operation were made clear by a blackboard drawing. At the conclusion of his demonstration, Dr. Primrose was highly complimented by Mr. Owen for his lucid exposition of his subject.

Recent Pathological Studies of the Blood.—The last paper on the evening of the first day was a most interesting and instructing one by Dr. L. H. Warner, of Brooklyn. At the commencement of his paper he asserted that he believed there was a necessity for ex-

periments for the progress of pathology. His experimental researches were directed along three lines of inquiry, viz.: experiments, observation, and individual observation at clinics in hospitals. He considered that the examination of the blood in most cases was of more importance than an examination of the urine. Dr. Warner gave the formula of a new staining-solution which he had found very practicable: The blood specimen should be prepared in the regular manner. The slides were heated in a hot oven to 98° F., and immersed for one minute in a one-per-cent. aqueous solution of methylene blue, washed in water, then put in a one-per-cent. alcoholic solution of eosin, washed again with water, and then placed in a one-per-cent. solution of Bismarck brown. Dr. Warner's paper was illustrated with suitable diagrams.

President's Address.—On the afternoon of the second day, with a packed hall for an audience, Dr. Powell delivered the annual presidential address. He first recited a few reminiscences, when on former occasions the Canadian Medical Association had convened in the capital city; that was in 1871, 1881, 1889, and 1893. He referred to the South African war in order to show the unsatisfactory condition of affairs which permitted other colonial surgeons from Australia and New Zealand to practise their profession in that land without hindrance, while Canadians were debarred from the same privileges. An earnest and united effort on the part of the profession throughout the whole Dominion of Canada, in an endeavor to bring about inter-provincial registration, would facilitate matters in the direction of securing these privileges for the Canadian profession in other parts of the British empire. The hackneyed subject of tuberculosis was lightly touched upon; while a very important matter relating to the profession, that of a Medical Defence Association, was dealt with at considerable length. Dr. Powell favored the formation of such an association, and later on in the proceedings nominated a committee to look into the question, to report on the advisability and practicability of forming a Dominion association of this character.

Some Experiences in the Treatment of Hernias.—Dr. F. J. Shepherd, of Montreal, contributed this paper. He said that some twenty years ago surgeons began to perform these operations by the open method. Older methods in vogue were touched upon and described; and he instanced one very large hernia which had come under his observation then, when the man could not put his trousers on. The methods of operation were almost as numerous as were surgeons, but there were certain general principles underlying all operations: (1) The necessity for excision or obliteration of the sac; (2) closure of the canal; (3) union by first intention. Some also held that alteration in the direction of the canal was necessary. The operation performed by Dr. Shepherd was Bassini's, but with it he was not always successful. He had used all kinds of sutures. Absorbable sutures were the best, and if aseptic they were to be preferred. A suture that would last for three weeks was all that was wanted. He had used chromicized catgut now for some time. He never washed out the wound, and thought it better to dissect out the sac with the knife than to tear it with the fingers. He never used a drain. For the past two years, he had used rubber gloves in all his surgical work abdominal in character, and he considered that he had got better results since he began their use. In hernia operations, the mortality was practically *nil*. Operations on children were now the most successful cases; formerly they were not advised except in strangulated cases.

Dr. Lapthorn Smith discussed this paper and the cases described, although his experience lay mostly in ventral and umbilical work. In some of this he had seen hernias so large as to require twenty stitches. During the past two years he had abandoned silk and resorted to chromicized catgut, which he always prepared himself.

Replying to the criticisms, Dr. Shepherd stated that if there was any oozing in the wound, he would pass a probe between the edges of the wound to let out the accumulated serum. This way he found to be quite efficacious, as thus the chance of the introduction of any germs from without was minimized.

A Case of Sypilitic Gummata of the Spinal Cord Successfully Treated by Enormous Doses of Iodide of Potassium.—Dr. F. W. Campbell, of Montreal, reported the history of this very interesting case. It occurred in a man of highly neurotic temperament, who a short time before the onset of symptoms of a definite character had suffered from repeated attacks of insomnia of a very aggravated character. When his sickness began, there were noticed retention of urine and loss of power in the lower limbs. The patellar reflex was about normal. The loss of power in the lower limbs was absolute. The pulse varied from 80 to 96; the temperature was never above 99° F. The stomach remained in fairly good condition all the time. A consultant from New York was brought on, and a diagnosis was established of tumor of the spinal cord situated about at the first lumbar vertebræ, which might be sarcomatous or syphilitic. The advice of the consultant was to give gr. d. of iodide of potassium per day, commencing with one drachm three times a day. Dr. Campbell detailed minutely the daily history of the patient while getting him under the large dose, and then again while it was gradually being withdrawn. The patient was alive to-day and in good health, having recovered complete control of his lower extremities.

Address in Gynæcology.—A very practical address was delivered by Dr. William Gardner, of Montreal, on the mistakes in diagnosing gynæcological and obstetric cases. He said that we often learned more from our mistakes than we did from our successes. Correct and accurate diagnosis depended mainly upon the sense of touch, which could be attained only by long and patient practice. He referred to the advantages of examining on a plain table instead of on a couch or bed. The patient's rectum should always have been emptied before she presented herself for examination. As for the bladder, it was best for one to empty that viscus himself per catheter when the patient was on the table, as in this way one would be able to notice any discharges, etc. That the physician would have to do this often was quite clear from the fact that there were many women of nervous temperament who would not be able to empty the bladder voluntarily in the physician's office. Another advantage of doing this for one's self was that an uncontaminated specimen for examination was obtained. In cases in which tension was present in the muscles of the abdomen, if a series of circular movements over the lower abdomen were made, gradually narrowing the circle, one would be able to overcome whatever rigidity might be present. Dr. Gardner urged caution in the use of the uterine sound. He considered it a rather dangerous instrument, so that its use ought to be extremely limited, and held the opinion that many women had lost their lives through this instrument. Then there were the danger and risk of infecting and injuring the uterine canal. This sound was a great deal too much employed by the general practitioner. Mistakes in diagnosing displacements of the uterine body he considered to be the most common. The uterus was a very movable organ, and a distended rectum or bladder might cause it to be diagnosed as an ante- or a retroversion. Then it was important to remember that it might be displaced through acts of coughing, vomit-

ing, etc. In all examinations of the pelvic organs, Dr. Gardner had made it a point to examine the position of the kidneys as well. Referring to examination by the Sims method he said it was necessary to have the patient in the proper position; and if one had not a Sims speculum, a bent table-fork or the finger of the opposite hand could be used to distend the perineum. Mistakes were often made in the diagnosis of pregnancy; but still the patients were few in whom the diagnosis could not be made by careful examination of history, signs, etc. Many women were probably inaccurate as to date. Dr. Gardner illustrated his points as he proceeded, by reciting cases. One in particular he instanced, when he once found a woman in his office on her hands and knees in the throes of a twin labor, which a fellow-practitioner had failed to recognize and had tapped the gravid uterus and drawn a quantity of the liquor amnii. Dr. Gardner spoke of the mistakes made by himself as well as by his brother practitioners. The close of the paper referred to an interesting account of mistakes which had occurred in diagnosing extra-uterine pregnancy.

The association tendered him unanimously a hearty vote of thanks for his exceedingly practical paper.

An Unnoticed Factor in the Production of Abdominal and Pelvic Disturbances in Women.—Dr. Clarence Webster, of Chicago, contributed an interesting paper with the above title. Symptomatology in women, he said, was often overlooked by the general practitioner. The question of the normal relationship of the abdominal and pelvic contents was dwelt upon, and then he proceeded to account for intra-abdominal pressure, holding the view that the pelvic as well as the abdominal organs were to a large extent held in their respective positions by reason of the pressure of the abdominal and pelvic walls. He stated the average specific gravity of the viscera to be a little more than that of water; that of the liver was 1.5. He maintained that there was no proof that the mesenteries acted as constant supports or were ever meant to be such; and the main factor in sustaining the viscera was the strength of the abdominal wall and pelvic floor. Local weakness of the abdominal wall had been fairly well described under hernia, while general weakness of the abdominal wall had been described as pendulous belly. General weakness in his experience was an exceedingly rare condition. As to the question of etiology, this condition was found in women who had borne children; and so, on examination of the great majority of women, there was found some degree of separation of the recti muscles in the region of the navel. All evidence later on might disappear, but permanent widening remained. The results of all this was unavoidable enteroptosis; and this was generally found in women who had been addicted to the pernicious habit of tight-lacing. A very common displacement seen was that of the right kidney. Dr. Webster dwelt upon the diagnostic symptoms of these conditions, and then proceeded to describe the operation he performed for their relief. This consisted in bringing the edges of the two recti muscles into apposition. He first performed this operation in November, 1898. Since that time he had operated upon forty-one cases, and the results had been most satisfactory in all.

Mr. I. H. Cameron took exception to Dr. Webster's using the word "unnoticed" in the title of his paper, as he thought this was not an unknown factor in the production of the conditions mentioned.

Dr. W. S. Muir, of Truro, N. S., asked what leaving off the use of the binder after confinements had to do with the production of these conditions.

Dr. Webster held to the opinion that this had not been noticed except by himself, and challenged Mr. Cameron to quote authority otherwise. The absence of the binder in his opinion had not made any special difference.

Address in Medicine.—Prof. S. F. Shattuck, of Harvard University, said in opening his address that there was noticed a subdivision of labor in every branch of industry. As a consequence, specialization had taken place in the science and art of medicine. In specialization lay the cleavage between medicine and surgery; and nowhere had the line been more closely drawn than in England. Anæsthesia had greatly enlarged the bounds of surgery. Twenty-five years ago there was not a pure surgeon in America. Bellyache was now a surgical disease. The heart was practically the only viscus which remained the exclusive property of the physician, and he was not so sure but that even this organ would soon be attacked and we might hear of suturing of the mitral valves. In this country the general practitioner was clinging to obstetrics for family practice. In some of the larger centres, there was now even a tendency to specialism in obstetrics, when the specialist would preside at the accouchement, and the family practitioner then step in to oversee the attendance throughout the puerperium. Pure gynæcology scarcely existed to-day, and pelvic tinkering was suffering from a rapid decline. The great bulk of major gynæcology was nothing more than abdominal surgery, which properly belonged to the general surgeon. Gynæcologists should study general surgery and become general surgeons first. The field in medicine was so large that no one man could grasp it all in a lifetime. Other specialties were referred to. The desire on the part of some to escape the hurly-burly of general practice might be a cause in throwing them into special lines; and then there was the fact that special knowledge drew larger fees. Ophthalmologists got more for removing a speck of dust from the eye than did the general practitioner. Since we had specialists for diseases of the young, why not also have a specialty for the diseases of the old? In the belief of the speaker specialism had come to stay.

The gathering was exceedingly delighted with the deliverance of Dr. Shattuck, and at the close tendered him a cordial vote of thanks, to which he made an appropriate reply.

Gastric Hemorrhage.—This paper was read by Dr. George E. Armstrong, of Montreal, who said he believed there was a fairly well-determined field in which surgical interference might be of use in hemorrhage of the stomach. Hemorrhage occurred in fifty per cent. of gastric ulcers and was fatal in eight per cent. Cases were arranged in two groups, the acute and the chronic. Rodman had reported thirty-one operations for frequently occurring or chronic hemorrhages, with six deaths. The speaker had operated five times for gastric hemorrhage, one being a chronic case. In one of these the patient was getting along nicely after the operation, when she expired suddenly; and on a post-mortem examination being made, thrombi were found in the branches of the pulmonary artery.

Some Cases in Stomach Surgery—Gastrotomies, Two Cases; Gastro-Enterostomies, Two Cases; Pylorectomy.—Dr. A. E. Garrow, of Montreal, reported these cases. In one patient operated on, the patient was fed before he left the operating-table. Another, a woman aged fifty years who had a persistent hacking cough, had gastrostomy performed, and was discharged able to feed herself through a tube. In another case, in a man aged thirty-three years, who had vomiting and blood in the stools, the patient suddenly felt acute pain and became pale. Duodenal perforation was present, and when the abdomen was opened, gas escaped from the incision. When discharged on July 24th last, the patient was feeling well. Six cases were reported.

The Modern Treatment of Retroversion and Prolapse of the Uterus.—Dr. A. Lapthorn Smith presented an able paper with the above title. It referred to the proper and most successful management of procidentia uteri in elderly women between seventy and seventy-five years of age—a most pitiable condition. Except for this trouble, the patient might be otherwise in excellent health; the perineum, however, was so relaxed that no pessary would remain in place. Then in the majority of these cases there was an ulcerated cervix. After confinement the uterus remained large, and the pernicious habit of keeping women too long on their backs had a tendency to produce the backward displacement. Dr. Smith felt certain that women who had been relieved of this distressing condition would have little difficulty in persuading others to avail themselves of the treatment. He removed a woman's uterus a few months ago, which had been out of her body for twenty years; and the patient now assured him that she felt like a young woman. In correcting this deformity, Dr. Smith made a small incision in the abdomen and performed ventrofixation. After that the vaginal canal was narrowed by a large anterior and posterior colporrhaphy. In selected cases, he also amputated the lower half of the organ and then stitched the vagina to the upper half. He considered ventrofixation, if properly performed, a most reliable means of fastening up the uterus. The operation had given him the most complete satisfaction of any operation he had ever performed, especially when combined with amputation of the cervix and posterior colporrhaphy.

Gasoline as a Surgical Detergent.—A highly original paper was contributed by Dr. Bruce L. Riordan, of Toronto, on the use of gasoline as a detergent. With this the dirty, greasy hands of machinists, who are the subjects of injuries in these parts, could be effectually and rapidly cleaned, without the ordinary brush and soap and water. It was far better for this purpose than any method heretofore devised for cleansing. He now constantly carried a small bottle of this in his surgical bag. A report from Dr. William Goldie, of Toronto, showing its effects upon germs and germ life, would conduce to its employment as indicated. One word of caution was thrown out by Dr. Riordan as to its use; as it was a highly inflammable substance, it should not be used in any quantity near an exposed light; and then it was painful in the eyes or ears. It was also useful in cleansing sutures of accumulated serum, blood, and dressing-powder, thus freeing these particles and enabling one to locate the stitches more easily and quickly.

Dr. J. C. Mitchell, of Inniskillen, Ont., stated that he had tried gasoline recently as a detergent in two very severe threshing-machine accidents, in which the parts were all smeared over with oil and grease and dirt; and it was very satisfactory, as he was able to get perfect cleanliness in a short time, both wounds healing by first intention.

Dilatation and Prolapse of the Stomach.—Prof. Alexander McPhedran, of Toronto University, presented this paper, which dealt principally with prolapse. This condition rarely occurred alone, but was associated with prolapse of other abdominal organs. There was generally present as well some degree of dilatation, and the abdomen might be prominent or flat, or even retracted. The case of a man aged fifty-one years was referred to, a manufacturer, who had been ailing for two or three years. The stomach was below the umbilicus. He was directed to massage the abdomen very thoroughly and to practise abdominal gymnastics. Through this treatment, combined with dietetics and some strychnine, he had been restored to health and was able to resume business. Another case of a woman aged thirty-five years was reported. This woman had been the subject of recurrent attacks of vomiting for two years. The symptoms were detailed; massage and abdominal gymnastics were ordered with satisfactory results. The different ways of examining the stomach were described, and in concluding Dr. McPhedran spoke of the benefits of a change of scene in treating these cases.

Physical Training; its Range and Usefulness in Therapeutics.—Dr. B. E. MacKenzie, of Toronto, gave a very interesting account of the methods employed by him in correcting deformities in his orthopedic hospital in that city. The paper was illustrated by lithographs showing improvements in spinal deformities after physical training in the direction indicated. The paper embraced the results of his observations for thirteen years past, and was ample justification of the benefits derived from gymnastics in the correction of lateral curvature, club-foot, etc. He had also found physical training valuable in hysteria and chorea, especially the former.

Inter-Provincial Registration.—Dr. T. G. Roddick, M.P., read the report of the committee having this matter in hand. A new feature to be incorporated in the measure was that of allowing the homœopaths representation on the proposed Dominion council, as, according to the law of Ontario, these had their vested rights in that province, and so must be accorded similar interests in any proposed Dominion council. These would be allowed three representatives, which would be equivalent to the representation from any one province of the Dominion. Their term of office would be four years. Homœopaths, however, as such, would not be mentioned in the measure, but they would be classified under "any other school of medicine having legal recognition in any of the provinces in Canada," as the British Medical Council would not recognize any such body. Dr. Roddick stated that the bill would be introduced at the next session, and advised the members of the committee from each province to bestir themselves before their respective provincial parliaments, as these bodies must sanction the measure before it can be finally acted upon by the Dominion Parliament.

Cerebral Abscess.—Dr. James Stewart, of Montreal, reported two interesting cases of abscess of the brain situated in the temporo-sphenoidal lobe, and referred to the unusual existing aphasia which was present in both cases, viz., simple inability to name objects. The first case occurred in a young man of twenty-two years who had otitis media following an attack of influenza. Some six weeks afterward an abscess formed. The abscess was diagnosed as being confined to this area simply on account of the peculiar aphasia—the simple inability to give the name of a pen when that object was presented to him. The patient was operated on by Professor Bell, who secured two ounces of pus. Meningitis, however, set in, and the patient died. The second case was that of a girl of twenty-one or twenty-two years of age. She had had ear trouble for a great many years, with very severe pain at times. She too had difficulty in naming objects, and finally she could not name any object whatever. She died suddenly a few hours before the operation was to be performed for her relief. On the opening of the skull at the subsequent post-mortem examination, two abscesses were found, one skirting the upper margin of the lobe and the other situated about the centre thereof.

In reply to a question of the president, whether we were to take this kind of aphasia as a distinct diagnostic symptom of abscess in that region, Professor Stewart stated that there was what they called a "naming centre," and when this was destroyed that particular form of speech defect was present. The cases were aptly illustrated by a diagram.

Gangrene of the Leg following Typhoid Fever.—Dr. H. H. Chown, of Winnipeg, reported two cases of gangrene of the leg following typhoid fever, which had recently come under his observation. In the first case the patient had the classical symptoms of typhoid fever, the spots appearing at the end of the first week and being very numerous. There was great pain in the calf of the leg, with collapse symptoms, while the limb was cold and bloodless. Cutaneous sensibility was lost over the leg. The third day after the complication set in the part involved included the lower third of the leg on the inner side and the lower half of the outer. Operation was done at the junction of the upper and middle third of the femur. The patient stood the operation well. The temperature before the operation was 102.6° F.; the pulse was 120. On the following day the temperature was normal and the pulse 110. On the tenth day the flaps were united. There was a rise of temperature a few days later—a relapse, with hypostatic congestion of the lungs. On the fifth day after there was hemorrhage of the bowels. The patient was now a picture of health, weighing two hundred pounds. The second was a somewhat similar case, in which the blood reacted early and promptly to the Widal test. The gangrene began in the first case on the eleventh day of the disease; in the second on the ninth. Keen had reported gangrene on the fourteenth day. The gangrene in the second case extended to the upper and middle third of the leg. The leg was amputated, and prompt union took place throughout.

Dr. R. B. Nevitt, of Toronto, discussed these cases and mentioned a similar case coming under his observation during the past summer. Gangrene occurred in his case about the third week of the fever, and the patient was seen about a week or ten days thereafter. Amputation was performed through the middle third of the femur. He also referred to a case of gangrene of the arm following an attack of pneumonia, recently observed by him.

Notes on Atropine.—An interesting paper was contributed by Dr. R. D. Rudolf, of Toronto University, which was illustrated by means of a chart showing the action of the drug on animals and the inferences drawn therefrom of its therapeutic uses. He found that the drug directly stimulated the heart, and thus the blood pressure was markedly raised. He considered the maximum single dose as laid down by Witherstine, of gr. $\frac{1}{20}$, as too large unless used as an antidote; and he thought that one ought never to give more than gr. $\frac{1}{100}$ of atropine sulphate at one time except in emergencies. He also referred to its action in catarrhal pneumonias of children, and its employment before anæsthesia to ward off danger.

The paper was discussed by Dr. A. D. Blackader, who congratulated Dr. Rudolf upon it, and said that he hoped he would pursue his studies further upon the same subject to find out the effect produced by atropine in controlling vomiting after anæsthesia. He considered, however, that strychnine and not atropine was the most powerful heart tonic in our possession. He thought that late experiments would throw doubt upon atropine being a direct stimulant to the heart muscle, and thought it would be questionable practice to administer a drug that would paralyze nerve endings, when it was desired to stimulate the heart's action.

Lantern-Slide Demonstration of Skin Diseases.—The demonstration of these cases was conducted by Dr. George H. Fox, of New York City, and proved to be one which the members of the association thoroughly appreciated. The great majority of the skin lesions shown were of syphilitic origin; and as they appeared on the canvas Dr. Fox described the histories of the cases. One in particular was remarkable from the disfigurement of the woman's face. It was a large mass of excrescences on the nose, which Dr. Fox was able to get rid of in the course of two or three months, leaving only a slight superficial scar. He laid down a timely word of caution in treating syphilitic conditions, that when the patient was run down and emaciated through large doses of mercury or iodide of potassium, one should not continue pushing these drugs, but should desist for a time, and in the interval endeavor to build up the patient's strength and general condition. That accomplished, the specific treatment should be resumed, and the results would be found to be more beneficial.

At the conclusion of the doctor's demonstration, which will rank as one of the features of the meeting, Dr. Fox was tendered a cordial vote of thanks for his instructive work.

Dr. F. J. Shepherd showed a very interesting case, that of a boy of sixteen years, who at the age of six sustained a severe cutting injury of the nerves and vessels of the axilla, all the nerves of the brachial plexus below the cords of the brachial plexus being severed completely. At that time, ten years ago, Dr. Shepherd dissected out each nerve separately and united their respective ends by suture. All did well with the exception of the musculo-spiral; as a consequence, the lad exercised very little control over the extensors of the forearm.

The Successful Treatment of Two Important Cases of Disease of the Eyes by the Combined Methods of Mercury and Iodide of Potassium Internally and Pilocarpine Hypodermically.—Dr. C. H. Burnham, of Toronto, reported two cases successfully treated by his combined method. No such result followed other plans of treatment, and with this plan a permanent result was got. This treatment had a wide application. Whenever iodide of potassium and mercury or the iodide alone was given internally in suitable cases without satisfactory results, if the pilocarpine was added good results would always follow.

Mental Sanitation.—Dr. R. W. Bruce Smith, assistant superintendent of the Brockville Asylum for the Insane, contributed a scientific paper with the above title. It was a plea for prophylaxis in insanity, and he thought that much would be accomplished in this direction during the twentieth century. Insanity was on the increase in Canada, and it could be ascribed to the fact that while these unfortunates were well attended when they become insane, the fact that there had been no preventive measures employed spoke for itself. In order to accomplish good in this direction, we must seek either to lessen the demands on the brain, or to strengthen its resisting-power. He condemned intermarriages in families and also among those of a deranged mentality. Fifty per cent. of the cases of insanity were hereditary, and the descendants of these persons should be careful in contracting marriage ties. He referred to a portion of one county in Ontario alone, where indiscriminate marriage and intermarriage had become most fruitful; he had seen several members of one family from that locality inmates of the same institution at the same time. He considered that the day would yet dawn when the same attention would be given to the rearing of children as was now given to the breeding of horses. Speaking of farm life and the tendency it had to induce melancholy, he thought this class of the community should receive education by participating more in the enjoyments of life and not continue to rot in domesticity. An upheaval in the sentiment and surroundings of the rural homes would work wonders in prophylactic principles.

Anti-Consumptive League.—The Canadian Medical Association indorsed the scheme for the formation of a Dominion Anti-Consumptive League. The

following were recommended as provisional officers: *President* (honorary) the governor-general; *President*, Sir James Grant, of Ottawa; vice-presidents were appointed for all the provinces; the secretaries are to be the secretaries of the different provincial boards of health. *Secretary-Organizer*, Rev. Dr. Eby, of Toronto; *Treasurer*, J. N. Courtney, Esq., deputy finance minister of Ottawa.

The Medical Defence Association.—The association recommended that Dr. V. H. Moore, of Brockville, be the permanent chairman of the committee. One member for each province was appointed. This committee will gather information on the subject and bring in a recommendation at the next annual meeting.

Election of Officers.—The following officers were elected: *President*, H. H. Chown, of Winnipeg. *Vice-Presidents*—Prince Edward Island, H. D. Johnson, of Charlottetown; Nova Scotia, A. J. Maiter, of Halifax; New Brunswick, T. D. Walker, of St. John; Quebec, A. Lapthorn Smith, of Montreal; Ontario, A. A. Macdonald, of Toronto; Manitoba, J. A. Macdonald, of Brandon; Northwest Territory, J. D. Lafferty, of Calgary; British Columbia, S. J. Trinstile, of Vancouver. *Treasurer*, H. B. Small, of Ottawa. *General Secretary*, E. N. G. Starr, of Toronto.

Sir William Hingston and Dr. F. W. Campbell, of Montreal, were appointed on the board of governors of the Victorian Order of Nurses, as representatives of the Canadian Medical Association.

The treasurer's report showed that one hundred and fifty-three members were in attendance, and that there was a balance in the treasury of $240.65.

The next place of meeting will be Winnipeg.

Medical Items.

Cholera in India.—Cholera is devastating Western India in an alarming manner. The death returns are truly appalling. The epidemic is pursuing its course through the area under British rule as well as in the native states. To comment on the tragic significance of the weekly death roll would be superfluous. The dreadful facts speak for themselves. It is natural to connect the appearance of the complaint among the sufferers from famine with that scourge, but it is equally severe at long distances from the zone of dearth. Apart from the mortality and suffering involved, the officials who minister to the wants of the stricken people are almost in despair as to what to do for the best. Those engaged in the Indian service have brave hearts and no doubt will conquer in the end, but it is enough to make angels weep at this last load of misery.—*English Public Opinion.*

Modern Small-Bore Rifle Bullets.—Dr. Clinton Dent, who has recently returned from service as a surgeon with the British army in South Africa, read a paper at the meeting of the British Medical Association on the effect of wounds by modern rifle bullets. The London *Lancet* reports his remarks as follows: Broadly speaking, bullet wounds of all kinds in the South African campaign had done well. Recoveries from very severe wounds had been numerous, and many of these recoveries had been most remarkable. The percentage of wounded men who had been found fit to return to duty had been unusually high. Wounds inflicted causing permanent disability had been less frequent, and injuries the consequences of which necessitated amputation had been proportionately fewer than in previous wars. Conservative surgery had most probably been carried further and with more successful results than in former campaigns. These satisfactory results had been ascribed mainly to the "humanity" of the modern small-bore bullets. He believed that the surgical healthiness of the climate of South Africa and the widespread employment of the "open-air" method of treatment had quite as much to do in bringing about this most satisfactory state of affairs. Septic complications attacking either bullet or operation wounds had been very rare. The idea that the heating of the bullet had any influence was probably universally discarded. The heating effect was never seen even when bone was struck; although arrest of motion was possibly the mode of transformation of motor energy into heat, yet its effects were not seen. Again, the bullet, even if made white-hot by aerial friction, passed far too rapidly through the tissues to have any cauterizing effects. The "hydrodynamic" theory as explaining the destructive effects of certain bullet wounds has now few adherents. As instances of cases in which military surgery was now much more conservative than formerly might be cited perforating abdominal wounds, compound fractures, wounds of joints, and nerve injuries. All wounds did well, even shell wounds; the only joint wound which did not do well was that of the ankle. Among injuries in which surgery was now much more active were those of the head, which nearly all had to be and were operated on, and with success.

Dangers to Public Health from Railway Carriages.—Mr. Durant Cecil, a civil engineer, read a paper upon this subject at the Congress of the British Institute of Health lately held at Aberdeen. In the course of his remarks he said that the difficulties and costliness of properly cleansing carriages were illustrated a short time ago by a report made to the corporation of London by the medical officer of health, describing the means employed to cleanse and disinfect a carriage in which a person suffering from small-pox had travelled. The whole carriage had to be completely dismantled. As to the shutting up of carriages as soon as they have been vacated by passengers, strong and authoritative and reiterated protests are needed. There are wonderful remedial forces in nature if only we would give them free scope and harmonize our artificial arrangements with their health-giving, life-renewing action. This shutting up of carriages belongs to the same category of benighted prejudices as the drawn-down blinds and closed windows of houses.

Heredity and Imitation.—The social sciences have always been ardently pursued and brilliantly expounded in France, and nowhere have the doctrines of Darwin and Spencer received a warmer welcome. Indeed, fifteen years ago, when Oxford lecturers were riddling Spencer with criticism, he ruled the Latin Quarter like a sultan. But of late there has been, as elsewhere, an effort made to delimit with greater accuracy the sphere of hereditary transmission. In the field of strict biology Weissmann has denied the transmission of acquired quality. In the field of sociology a young French thinker, M. Tarde, whose singular union of philosophic insight and expository power reminds one of De Tocqueville, has called attention to the importance of the social as distinct from the biological factors. M. Tarde does not, of course, deny the influence of hereditary transmission or the biological basis of social life, but in the brilliant volume entitled "Les Lois d'Imitation," he points out that the biological force is continually supplemented and corrected by the social force of imitation. The racial factor is not presocial, insoluble, persistent, nor is the ultimate term of human progress a world divided into highly differentiated social groups. On the contrary, man is essentially imitative and goes through life

like a somnambulist, unconsciously registering and imitating the desires, the thoughts, and the actions of others. Every day the world is becoming more similar, not, as De Tocqueville thought, because of democracy, but because a series of inventions has increased the imitativeness and the "imitativity" of man. Society is, in fact, "the organization of imitativity," and perfect and absolute sociality would consist in an urban life so intense that a thought once conceived by an individual would be immediately communicated to his fellow-citizens. The prospect is appalling, but that, of course, is not to the point. The process of biological evolution is slow, the process of social evolution is very often surprisingly rapid. How many centuries did it take to develop the wing of the eagle? How many months to modernize Japan? Social progress, then, as distinct from biological progress depends upon the discovery and diffusion of inventions, some of which, such as Christianity, are substituted for old inventions, while others, as telegraphy, are added to them.—*London Speaker.*

Garbage Disposal in China.—Consul Fowler says: "The cleanest cities in China are Hang-Chow and Ning-Po. In the centre of these two cities I have myself seen dogs eating bodies of babies; the rotting corpses of cholera cases; snakes winding in and out—in fact the most horrible filth on one side, while across the way was the glitter of gold, pomp, and luxury."

First Aid for the Wounded.—The Vincennes annex of the Exposition, notwithstanding its distance, attracts quite a crowd of people every Sunday to witness the sports and the international competition of physical exercises. One Sunday, a few weeks ago, the spectacle offered to those who wended their way toward the municipal velodrome was both novel and picturesque. Their programme announced an international competition of aid to the wounded. The various societies proceeded in turn to the installation of relief stations, which the public were afterward allowed to inspect, and which comprised all the usual material—carriages, harness, and various apparatus designed for the carriage of the wounded. Then the competitions proceeded with exercises in lifting the patients and dressing their wounds. Several obstacles had been set up upon the lawn of the velodrome, such as walls, hedges, and taluses. Here and there were seen young men seated or lying flat upon the ground, the victims of an imaginary battle, and bearing placards that indicated the nature of their wounds. Then came the relief corps with their litters, antiseptics in bags, and bottles and rolls of linen, wadding, and lint, and lifted each wounded person and bandaged his leg, arm, or neck with dexterity, rapidity, and delicacy. Then the patient was placed on a litter in a proper posture to spare the part affected. Then, more speedily than they had arrived upon the scene, the litter-bearers carried away the patient to the ambulance or hospital. In coming as well as going, it was necessary to surmount walls, hedges, taluses, and pass their burden over them gently and without shock.—*L'Illustration.*

Weight of Hydrogen Gas.—Lord Rayleigh has determined the weight of hydrogen gas dried by means of liquid air acting as a cooling agent. In recent experiments by himself and others phosphoric anhydride has been the desiccating agent, but a doubt remained as to whether on the one hand the removal of aqueous vapor was complete, and on the other whether some new impurity might not have been introduced. The object was not so much to make a new determination of the highest possible accuracy as to test whether any serious error could be involved in the use of phosphoric anhydride, such as might explain the departure of the ratio of the densities of oxygen and hydrogen from 16:1. The experiment proved that no serious error could result in this way.—*Proceedings of the Royal Society.*

Destruction of Rats by Means of Bacteria.—Loeffler has already advised the destruction of field mice by means of cultures of bacteria of bacillus typhi murium mixed with food, and the method has been carried out on a practical scale with some success. Danysz has used cultures of another species of bacillus in a similar way for the destruction of rats in the public sewers in Paris. The bacillus employed is one which Danysz isolated in investigating a spontaneous epidemic which occurred in field mice. When freshly isolated the organism was pathogenic to a certain extent for gray rats, killing about two or three out of every ten animals inoculated. It was found possible by artificial means to increase the virulence for rats to a much higher degree. The method employed for exalting and fixing the virulence was as follows: "A mouse was first killed by an ordinary inoculation; broth cultures from the mouse were then enclosed in collodion capsules, which were kept in the peritoneal cavity of a living rat for thirty-six hours. At the end of that time a subculture was made in broth and then passed through another mouse. This process having been repeated four or five times, the culture was passed first through the more susceptible young rats and then through adult rats. In the end a culture highly pathogenic for both the gray rat and the black rat was obtained. Pieces of bread soaked in broth cultures of the bacillus were then laid down in the sewers, and by this means a large number of rats were killed.—*Public Health.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 22, 1900:

MEDULLARY NARCOSIS DURING LABOR.

By S. MARX, M.D.,

NEW YORK.

In the preliminary report[1] on this subject, I was extremely conservative in my remarks. Further and ever-increasing experience makes me realize that in medullary narcosis we have a means of the greatest importance and of supreme scientific value, not alone for annulling the pains of labor but as a substitute for general narcosis, covering an enormous domain in surgery. It is of interest to note that this form of narcosis is not a new method. As far back as 1885 Dr. J. Leonard Corning, of this city, not alone suggested but carried to a practical termination the method about to be described. In a small book entitled "Local Anæsthesia," our distinguished countryman experimented on animals, and in one case in one of his patients, furthered suggestions which absolutely compel us to admit him as the originator of the operation for special anæsthesia with cocaine. He described his technique almost as it is carried on by us, except that he did not consider it essential to successful anæsthesia to enter the subarachnoid space. He simply introduced the needle between the spinous processes, and sent the solution in, "allowing it to become absorbed by the minute plexuses of veins and so carried to the cord." In this we do not agree; but more of this farther on. In this classic work, the author finishes by saying: "Whether the method will ever find an application as a substitute for etherization in genito-urinary or other branches of surgery, further experience alone can show. Be the destiny of the observation what it may, it has seemed to me, on the whole, worth recording." The prior claim to the operation must in all justice and honor be given to Corning, not alone because of his suggestions, but because of his original practical experiments in 1885. A number of papers by the same author appeared thereafter in rapid succession. These will form the basis of a historical review to be published shortly.

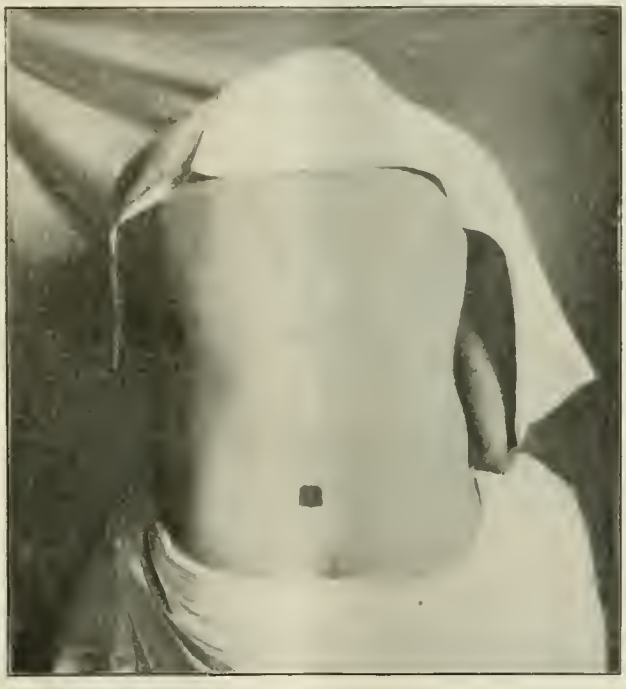

Fig. 1.—Dark Spot Marks the Spine of Fifth Lumbar Vertebra

I have used this method of anæsthesia in fully thirty cases, and there has never appeared any symptom which would make me apprehensive of either immediate or remote danger. In fact I never have had such smooth convalescences as since my experiments commenced. All the patients made ideal convalescences, and all the children alive before delivery were born alive and well, in spite of the fact that many difficult and trying labors were encountered.

Technique.—From an increased experience, the position of the patient for an easy, successful puncture is the exaggerated inclined one, *i.e.*, the scorching (bicycle) position. When for any reason the patient cannot sit up, a right- or left-sided posture with arched back, the head in an elevated position, is the next best one. When so placed there is a distinct curve in the lumbar region with the convexity downward. This has a tendency to increase the space between the individual vertebræ, and the puncture is made from the convex side. When the puncture fails, *i.e.*, inability to get spinal fluid, the other side may be tried. It is always absolutely necessary for successful anæsthesia to enter the spinal canal; in other words, a *sine qua non* to an absolute analgesia is the escape of subarachnoid fluid before the cocaine solution is injected. By the escape of fluid I am in positive position to state that the needle is in the space. There is no other absolute guide. My primary trials in the first three cases were absolute failures, for this important landmark was unknown to me and consequently omitted. Since I have depended on getting a fluid tap I have never failed to get a perfect anæsthesia. As a rule the puncture is very easily done, but in some few cases there has been the greatest difficulty in its performance. In one case six distinct punctures were made before the tap revealed fluid. In one case with an antecedent lumbar disease I failed absolutely, and was compelled to make the injection in the dorsal region, and then with good success. The operation was an abdominal hysterectomy, and when the abdomen was opened the lumbar lesion was readily noted.

The patient's back, from the coccyx to the middle of the dorsal vertebræ, is rendered absolutely sterile after the usual methods, even as the abdomen is sterilized before abdominal section. The parts are surrounded by sterile towels. A finely tempered needle, 10 cm. long, is employed with a solid metal hypodermic syringe, both of which are boiled for ten minutes. The patient having been placed in position, the thumb of the left hand is placed on the spinous process of the fifth lumbar vertebra. This point may readily be

[1] Medical News, August 25, 1900.

found by locating the deep depression between the spine of the fifth lumbar and first sacral, the posterior landmark of the external conjugate; or, in very fat women, a line drawn joining the highest points of the crista ilii will pass over the centre of the fourth lumbar vertebra and is a reliable guide. The needle is inserted immediately in front of and just outside the edge of the thumb at an angle of about 165°. The direction of the needle is slightly from below upward and without inward. If the point strikes the lamina it is to be moved gently up or down until the space between the vertebræ is felt. The point is pushed in very slowly and gently in a downward direction until the clear, limpid spinal fluid runs out drop by drop. If the tap brings pure blood it is, in my experience, beyond the canal, and gradual withdrawal will usually bring success. Should clogging of the needle be suspected, then it can be cleared by the stylet. Immediately fluid runs out, the barrel of the syringe is screwed on and the cocaine injected. From ♏ x. to xv. of a

Fig. 2.—Position as Needle is Being Introduced. Note position of thumb and its relation to needle.

two-per-cent. cocaine solution is used, representing between gr. $\frac{1}{3}$ to gr. $\frac{1}{4}$ of the salt.

Within from two to fifteen minutes anæsthesia is ushered in, occurring rather suddenly, occasionally preceded by a marked hyperæsthesia. Operating can usually be commenced as soon as firm pinching or pulling upon the labia minora elicits no pain. If at the end of fifteen minutes the desired result is not obtained, the injection may be repeated; or if, after complete anæsthesia, the sensation of pain returns, the same dose may be repeated. Thus I have injected three-fourths of a grain in one hour in a rebellious case without bad results. The cocaine solution to be efficacious must be freshly prepared, or else it becomes inert from frequent sterilization. Eucaine I have found valueless; Schleich's infiltration tablets I have found of little value. The area of anæsthesia varies considerably and cannot be influenced by either the dose given or the force with which the solution is thrown in. In some cases the whole body from the neck down is absolutely in an analgesic condition. In all cases the patient is void of sensation from the umbilicus down.

The anæsthesia lasts from one to five hours. Complications of a severe grade have never occurred. Disagreeable features frequently occur; in fact it is a rule to have them present, but fortunately their effect is very transient, lasting from eight to twenty-four hours. There are frequent nausea, vomiting, severe headache, profuse perspiration, chilly sensations, temperatures up to 102° to 103° F., probably all due to a shock to the central nervous system or to a disturbed intraspinal pressure, whether diminished or increased I am not prepared to state. Fortunately when severe these symptoms can be readily controlled by nitroglycerin gr. $\frac{1}{100}$ alone or combined with small doses of morphine. I have tried to anticipate these symptoms by combining morphine with the cocaine, but the results were not satisfactory. In fact in one case in which gr. $\frac{1}{6}$ morphine was injected into the canal, I got dangerous symptoms of morphine poisoning, showing how strong is the absorbing power of the spinal fluid. Lately I have had good results by injecting hydrobromate of hyoscine gr. $\frac{1}{200}$ as soon as the symptoms arose. In a limited experience with this drug I would suggest its use by the ordinary hypodermic method as soon as the cocaine is administered, or else its use immediately on the occurrence of the nausea and vomiting, which are always the earliest symptoms to arise after the puncture.

The physiology of the anæsthesia is not quite clear. Most probably the cocaine solution, thrown directly in contact with the lumbar plexus, deadens its sensibility or that of its important nerve roots (Fig. 3). The greater area of analgesia is probably due to rapid molecular absorption by the cord or its membranes. Motor disturbances so far as the uterus is concerned have not been noted. Uterine contractions go on regularly as if no narcotic had been used, the patient feeling no pain; and one is cognizant of the contractions only when the hand is placed on the abdomen. Reflex action of the abdominal muscle was found only when incomplete anæsthesia existed, and was then accounted for by the presence of pain. When analgesia was complete there was no spontaneous bearing down, and the muscles were not voluntarily called into action. Only on command did the patient bear down and bring her abdominal muscles into play as powerfully as in an ordinary case. Explorations, versions, extractions, placental removals were readily done, not with quite as great ease as under chloroform, but with greater facility than in a non-narcotized woman. I never noted a disposition to bleed, at least no greater than in an ordinary case. Is the operation associated with danger whether immediate or remote? There are two possible immediate dangers: (1) collapse from cocaine, (2) sepsis from the puncture. I have used as much as gr. $\frac{3}{4}$ of the drug within one hour, and have never noted any untoward symptoms. My average dose is about gr. $\frac{1}{4}$, the smallest gr. $\frac{1}{6}$, the maximum individual dose gr. $\frac{1}{3}$. The symptoms which follow all the injections are not due to cocaine, since they occur after an injection of a saline solution. It is possible that dangerous symptoms might arise in some cases from a special idiocyncrasy to the drug, since severe symptoms of poisoning have been noted after instillation of cocaine in the eye or nose. But I have never met them after lumbar injection.

(2) Sepsis. There is no denying the fact that, in unclean hands and with unclean instruments, this otherwise safe operation can and will produce a severe if not fatal sepsis. Any serous cavity invaded carries a certain profound risk. In the operation we penetrate dura and pia mater, and invade a canal freely communicating with a similar space in the brain, consequently a dangerous territory. Therefore we must surround our manipulation with every possible known safeguard. Asepsis of person, of instruments, of patient, of solution is the only safeguard, and this must be as carefully attended to as if the belly were about to be opened. The operation should be done only by one trained in surgical asepsis, or else surely

bad results will occur in the form of septic intraspinal complications. I have never, at least so far, noted any remote complications; but this may be due to the fact that my cases are too recent, the latest being about two months old. One useful point that my experience has taught me, in order to further the absolute success of operating under spinal anæsthesia, is to have perfect quiet while operating. Sight and hearing are unusually acute in these women. Apprehension is ever present, and a morbid fear that they might suffer pain causes not actual but psychical pain. This I have demonstrated on more than one occasion. To this end my audiences are told to refrain from talking, especially in reference to pain. The eyes of the patient are snugly bound, and the ears are thoroughly plugged with cotton. No unusual bustle is allowed, and instruments are handled so as to insure absolute quiet. The patient is constantly being reassured, and is interrogated by one person as to her sensations.

Indications.—I have carried a woman by repeated injections for eight hours through her labor with practically no pain. By improved methods and further observations it may be possible to carry a labor through from beginning to end under this narcosis. In multiparæ we must be prepared to inject when the os is three-fourths dilated, in the primipara when fully dilated. For purposes of exploration, either pelvic or fœtal, there is a field. In very prolonged and painful first-stage labors, when it is impossible for the doctor to sit for hours giving whiffs of chloroform, it would be ideal to give a lumbar puncture and relieve all pain and suffering for from one to five hours, and yet have the labor go on and the os dilate painlessly. Again a case might be imagined, in which both ether and chloroform are contraindicated, or a case in which no assistance can be had, and operating is absolutely necessary. A simple puncture is made, anæsthesia is complete, and the operator can attend strictly to his field of operating. In cases of threatened or already present convulsions, in which a simple examination would produce the spasm, a lumbar narcosis, lessening as it does peripheral nervous sensibility, might be of avail. Again in cases of sepsis, such as is noted in one of the cases cited below, one of profound nature in which both heart and kidney are affected, making the administration of a general anæsthetic dangerous, exploration and, if necessary, curettage could be undertaken. But at last, so far as we are concerned, it is a method ideally suited to mitigate or absolutely allay the dreadful pains of a normal labor, with no danger to the mother and none to the child, immediate or remote.

In the preparation of the report of these cases, I am deeply indebted to my very excellent house staff, Drs. W. R. Stone, M. M. Guillen, and W. P. Healy, for their very efficient assistance in all my work upon this subject. If it be remembered that our work has been almost entirely original, that references as to operative technique practically unknown to us, especially with reference to the absolute necessity for entering the spinal canal—all these various little details for furthering the success of our inquiries, must make evident the difficult work entailed upon all during the trying months of a hot summer. Again I must state that without so proficient and enthusiastic a house staff, the material for this paper would have been well-nigh impossible to obtain.

As an addendum, since writing this article, I feel that in the use of the hydrobromate of hyoscine, about

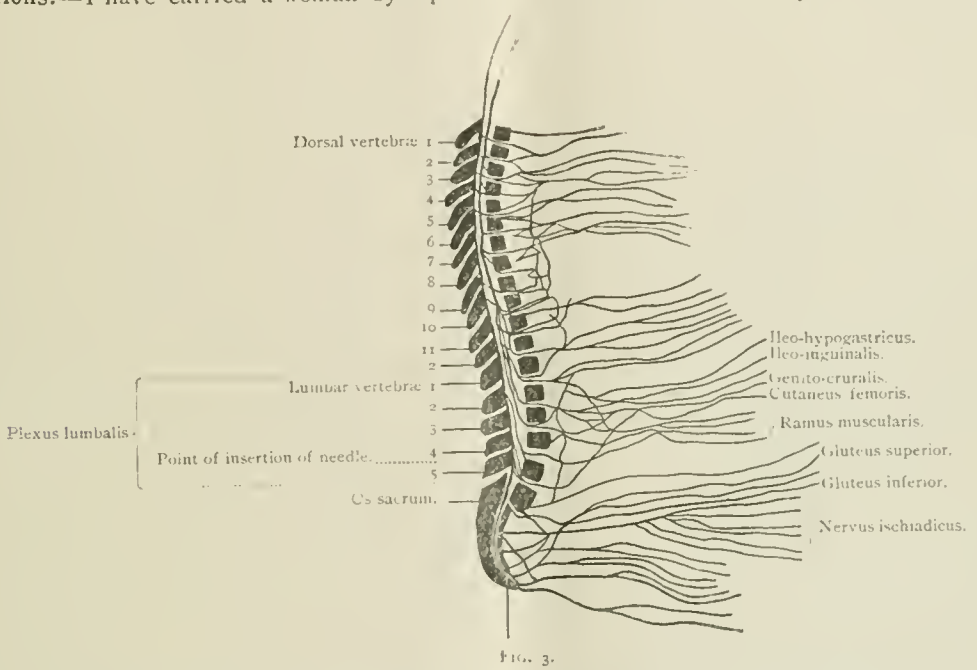

FIG. 3.

gr. $\frac{1}{200}$ given by the needle, we have a drug of the greatest utility in combating to a positive degree the post-operative symptoms arising from the cocaine puncture. If future results bear out past experiences, we have in the hyoscine a veritable specific.

CASE I.—H. B——, aged thirty-three years, multipara, anæmic, double femoral hernia. August 7th, in labor at 11 P.M., presentation L. O. A. August 8th, membranes ruptured 3:30 P.M., os fully dilated; 3:48 P.M., cocaine injected; 3:56 P.M., pain sensation dulled and delayed; 3:59 P.M., muscle and motor sense not affected; sensory paralysis complete below the level of the umbilicus; uterine contractions every two minutes; patient has no painful sensations; 4 P.M. child born spontaneously without the knowledge of the mother; 4:22 P.M., placenta born spontaneously, and after a lapse of ten minutes the mother asked if afterbirth had come. The following afternoon the temperature rose to 100.5° F., but fell to normal in eight hours. Three hours after the injection the patient experienced a tingling sensation in her legs and thighs. During the next ten hours a slight throbbing headache was felt, which disappeared in twenty-four hours without medication.

CASE II.—K. S——, aged thirty-five years, multipara; previous labors normal with a great deal of pain during the second stage; physical condition poor; patient has hydramnios to extreme degree. August 11th, 2:30 P.M., patient went into labor; 6 P.M., waters broke;

cervix present, os admits four fingers; head presenting above but fixed at brim. August 12th, 9 A.M., pains all night, no effect on os, contractions have now ceased. August 12th, 1:47 P.M., lumbar injection of gr. $\frac{1}{6}$ cocaine; 1:52 P.M., sensation to pain diminished and delayed; 1:56 P.M., absolute sensory paralysis below the umbilicus. Manual dilatation was begun, and during its performance the patient gave no evidence of knowing what was taking place. The operation was as easily carried out as under chloroform narcosis. The head was then above the brim. It was then decided to leave the patient unmolested to see if labor would proceed spontaneously without any complication. She was therefore put to bed, version or high forceps being abandoned for the sake of the experiment. In twelve hours the woman broke out in a profuse sweat. Temperature, 102° F.; pulse, 90; respiration, 60; slight headache. In twelve hours the condition returned to normal. The following day labor-pains again appeared, and in five hours the child was born spontaneously; normal, severe second-stage labor pains.

CASE III.—This proved to be a control test. S. D——, primipara, aged twenty years. August 12th in labor at 6 A.M.; in twelve hours os fully dilated; gr. $\frac{1}{6}$ cocaine injected; no effect whatsoever. In forty minutes another ℥ x. of the same solution was injected and still no effect. As the patient became very nervous and hysterical it was decided to use chloroform and deliver by forceps. Later on, having the cocaine solution tested by various methods, it was found totally inert. This case proved to be an excellent control test, as did the case in which the saline solution was used by mistake. Here also in three hours the patient complained of headache, tingling in the legs, slight nausea, and vomiting. In fourteen hours the temperature rose to 102° F.; pulse, 100; respiration, 28. Her condition returned to normal in eight hours.

CASE IV.—M. T——, aged thirty-eight years, multipara; condition excellent, previous labor normal. August 13th, 3 P.M., in labor; V. L. O. A., head in cavity; 3:48 P.M., cocaine gr. $\frac{1}{6}$ injected; 3:53 P.M., sensation below umbilicus delayed for pain; 3:55 P.M., total sensory paralysis below umbilicus. Patient had no knowledge of the uterine contraction, which occurred normally every two minutes; 4:28 P.M., head at outlet, and forceps applied without the patient being aware of the operation; 4:32 P.M., patient delivered; the mother was conscious of the traction alone; she wished to know why she was being pulled to the bottom of the bed. At 4:40 P.M., perineum repaired without pain; 4:55 P.M., placenta expressed; sensation of mother was as if something warm were passing through the vagina; 5:15 P.M., sensory paralysis still present; 6:45 P.M., sensation restored to lower part of body; 7 P.M., patient complained of intense throbbing headache referred to frontal lobes; 7:45 P.M., gave injection of morphine gr. $\frac{1}{4}$, nitroglycerin gr. $\frac{1}{50}$; patient felt cold and was shivering; 8 P.M., vomited; head symptoms less, rise of temperature to 101.5° F.; pulse, 88; respiration, 22; twelve hours later patient was in normal condition.

CASE V.—L. M——, aged thirty-five years, multipara, admitted to surgical ward with cellulitis of leg and thigh. August 18th, 10 A.M., membranes ruptured spontaneously; no labor pains. Transferred to septic ward; V. R. O. A.; os nearly dilated; prolapse of cord; pulsation 120 per minute; no contractions; 11:45 A.M., pulsation had fallen to 100; indication to deliver child; 12:45 P.M., cocaine injection, gr. $\frac{1}{6}$; 12:50 P.M., sensation of pain delayed and one minute later complete sensory paralysis; slight nausea and vomiting; burning sensation along spinal cord and feeling of cold in feet and legs; podalic version was performed without any pain to mother, although she expressed a feeling of suffocation when the hand was being introduced into the uterus; 1 P.M., child born by extraction. Mother had no knowledge of its birth. During the version the uterus contracted firmly around the operator's hand so that manipulation was very trying.

CASE VI.—R. M——, aged twenty-six years, primipara. August 19th, 9 P.M., labor began with rupture of the membranes, child presenting foot. August 20th, 6:30 A.M., os fully dilated; pains not severe nor frequent; 7:21 A.M., cocaine injection, gr. $\frac{1}{6}$. During the next thirty minutes the only change noted in the patient's condition was slight dulling and painful sensation; 7:51 A.M., injection repeated; patient complained of burning in lower extremities; nausea and vomiting; profuse sweat; 8:20 A.M., sensation entirely gone; hand introduced without pain, both feet brought down; 8:26 A.M., child delivered in usual fashion unknown to mother. A second child is found in utero; 8:50 A.M., hand introduced into uterus, macerated fœtus discovered; 8:55 A.M., child delivered, mother still oblivious of any pain or discomfort. The uterus continued to contract regularly and strongly up to birth of first child; 9:15 A.M., neither placenta having come away, the Credé method was unsuccessfully tried; 9:35 A.M., attempts were made in succession by the entire house staff to remove the placentæ manually, but because of the pathological adherence and the spastic contraction of the uterus it was found impossible to remove them. During all this manipulation the patient did not complain of pain or discomfort. Chloroform was now administered to the surgical degree. Dr. Stone then made the attempt, but it was still found impossible to remove the placentæ, as the same conditions obtained as during the cocaine analegesia, *i.e.*, placental adhesion and a spastic uterus. The uterus was accordingly packed with gauze, and the patient put to bed. At 2 P.M. I made the attempt to remove the placenta under local cocaine narcosis, gr. $\frac{1}{6}$; 2:08 P.M., sensation delayed and dulled; the hand was introduced and the placenta peeled off. The uterine contractions were not so strong as normal, nor did they materially interfere with the manipulation; 3:30 P.M., nausea and vomiting; sensation to pin-prick, dull; anæsthesia continues; 5 P.M., temperature, 100.8° F.; pulse, 90; same headache, but not severe; no medication was employed, and the condition became in every respect normal in twenty-four hours. This patient received half a grain of cocaine in less than seven hours.

CASE VII.—A. M——, aged twenty years; primipara; general condition excellent; full term, went into labor August 29th, 10 A.M.; pains strong and occuring every half-hour. At 8:30 P.M., patient was brought to the delivery room; pains strong and occurring every three minutes; cervix four fingers dilated; 9 P.M., pulse good and strong; 9:07 P.M., cocaine gr. $\frac{1}{6}$ injected into the spinal canal between third and fourth lumbar vertebræ; 6:09 P.M., complains of terrific cramps in legs and all through her; 9:11 P.M., nausea and vomiting; 9:16 P.M., sensation to pin-prick gone; 9:20 P.M., pain during uterine contraction is absent; 9:40 P.M., fœtal heart 130 per minute, clear and strong; mother's pulse, 80; 10:40 P.M., pain sensations still absent; pulse, 100; 10:50 P.M., patient seems to feel uterine contractions and bears down with them; 11 P.M., sensibility to pin-prick returning in legs; 11:10 P.M., patient is again having labor pains; uterine contractions for the last one and one-half hours have occurred every two minutes unknown to the patient; 11:24 P.M., cocaine gr. $\frac{1}{4}$ injected into spinal canal; 11:30 P.M., complains of cramps in her legs and coldness of the lower half of her body; she is nauseated; pain from pin-prick gone below the umbilicus; 11:32 P.M., patient is vomiting; 11:40 P.M., Magendie solution given hypodermically.

to quiet the vomiting; 11:45 P.M., sensibility to labor pains gone; 12:01 A.M., cramps in legs severe, have been present since 11:24 to more or less marked degree; 12:12 A.M., complains of pain over the symphysis pubis; pulse, 114; 12:25 A.M., complains of headache and great thirst; 12:48 A.M., perception of pin-prick as pain still absent; 12:51 A.M., labor pains are returning; pin-pricks not noticed; 12:56 A.M., chloroform administered and forceps applied; 1:11 P.M., child was born. The third puncture was not performed in this case, as the patient refused to permit it, saying that she did not care to vomit again; 2:50 A.M., patient has headache; post-partum temperature, 99.8° F.; pulse, 120; respiration, 30; 5 P.M., temperature, 100.4° F. August 31st, 5:10 A.M., temperature, 98.6° F.

Case VIII.—M. L——, aged seventeen; primipara; physical condition excellent, previous history negative; somewhat neurotic; went into labor September 6th, 8 A.M.; uterine pains slight, occurring every half-hour. Examination at 12 noon showed cervix conical and hard, admitting one finger. Patient had pains all the afternoon and night. At 10 A.M., September 7th, on examination, the cervix is thinned out and admits three and a half fingers; membranes intact and protruding. Position R. O. A.; presentation vertex; 11:47 A.M., cervix four fingers dilated; cocaine gr. $\frac{1}{3}$, morphine gr. $\frac{1}{6}$ injected into spinal canal at the third lumbar interspace; 11:53 A.M., uterine contractions not so painful; 11:57 A.M., patient complains of burning sensations in legs and feet; sensation of pain abolished as high as the umbilicus; 12 noon, uterine contractions strong, but patient is unaware of this occurrence; 12:15 P.M., feels nauseated and vomits; 12:20 P.M., vomiting continues; 12:50 P.M., patient again vomits; 1 P.M., complains of burning in feet and legs; is unconscious of uterine contractions; 1:20 P.M., is in a profuse perspiration; 1:40 P.M., cervix thin, dilated five fingers; "bag of waters" bulging; head well down but not fixed; 2 P.M., patient says she cannot see, feels as if she had been in a sound sleep and is just awakening; 2:20 P.M., pulse, 96; 2:36 P.M., pulse, 120; 2:46 P.M., cocaine gr. $\frac{1}{6}$ injected; 2:50 P.M., membranes rupture; 2:53 P.M., pulse, 120; 2:56 P.M., ordinary forceps applied without mother's knowledge; 2:58 P.M., axis-traction applied; 3 P.M., forceps removed after rotation had been made, the mother feeling only the traction; 3:05 P.M., low forceps reapplied, no pains with the tractions; pulse, 124; 3:10 P.M., child born; pulse, 120; 3:12 P.M., placenta removed manually, without pain to mother; 3:15–3:20 P.M., perineum repaired without pain; 4:10 P.M., patient carried to ward. Temperature, 100.6° F.; pulse, 106; respiration, 14. The patient was drowsy and showed contracted pupils; atropine gr. $\frac{1}{100}$ given; 7 P.M., complains of headache; strychnine sulphate gr. $\frac{1}{30}$ and atropine gr. $\frac{1}{100}$ given, also saline enema. Temperature, 102.2° F.; pulse, 100; respiration, 10; 12 midnight, atropine gr. $\frac{1}{100}$ given; respiration, 9. September 8th, 1 A.M., temperature, 101.6° F.; pulse, 112; respiration, 14. The patient is still drowsy; 5 A.M., temperature, 99.8° F., and then fell to normal, as did the pulse and respiration, where they remained after the iodoform gauze was removed at the end of twenty-four hours.

Case IX.—Y. L——, aged twenty years; physical condition excellent; in her seventh month of gestation; fœtus has been dead a week. At 11 P.M., August 27th, went into labor; pains irregular and infrequent. August 28th, 1 P.M., patient was brought to delivery room; os three and a half fingers dilated, cervix thinned out, and having pains every two minutes; 2:11 P.M., cocaine gr. $\frac{1}{6}$ was injected into spinal canal; 2:16 P.M., nausea and vomiting; 2:20 P.M., sensation of pain abolished below umbilicus; cervix dilating rhythmically and to a degree of four and a half fingers; diagnosis of macerated fœtus made; 2:25 P.M., cervix manually dilated, hand introduced into uterus; 2:30 P.M., macerated fœtus delivered; 2:56 P.M., placenta expelled with difficulty by modified Credé method; 3 P.M., the patient taken to ward and complains of slight dull pain in right leg. Temperature, 99.6° F.; pulse, 84; respiration, 26; 5:50 P.M., complains of thirst; 6:05 P.M., temperature, 102.6° F.; pulse, 92; respiration, 26; 9 P.M., temperature, 102 F.; pulse, 84; respiration, 26. Complains of severe headache; 11:20 P.M., still complains of headache; 1 A.M., August 29th, headache gone; temperature, 101° F.; pulse, 80; respiration, 24; 8 A.M., temperature, 99° F.; pulse, 74; respiration, 24. With the exception of a rise of the temperature to 100.6 F. at 5 P.M. the same afternoon, there was no further point of interest during the puerperium.

Case X.—M. L——, aged twenty-eight; Russian; primipara; physical condition excellent. The patient went into labor 11:30 A.M. September 3d, pains strong every fifteen to twenty minutes. Cervix soft, thin. Position, vertex R. O. P.; 6 P.M., cervix fully dilated; 6:08 P.M., cocaine gr. $\frac{1}{6}$ given by lumbar puncture with morphine sulphate gr. $\frac{1}{12}$; 6:11 P.M., has lost all pain sensibility below umbilicus. Uterine contractions continued normally, but painlessly; 6:23 P.M., child born spontaneously without pain to mother; 6:35 P.M., perineal tear (first degree) sutured, and 6:40 P.M., placenta expressed by modified Credé; 7:30 P.M., the patient is carried to ward, complains of heavy feeling in the head. Post-partum temperature, 100.2° F.; pulse, 116; respiration, 30; 9:30 P.M., complains of headache and vomited; ice cap to head for headache. September 4th, 1 A.M., temperature, 102 F.; pulse, 146; respiration, 48; 4 A.M., headache ceased; 1 P.M., temperature, 100 F.; pulse, 102; respiration, 24. September 5th, 1 A.M., temperature, 98.4 F.; pulse, 102; respiration, 24. Temperature has remained normal ever since this time. The remainder of convalescence was uneventful. The patient was discharged on the sixteenth day of her puerperium.

Case XI.—A. E——, aged thirty-eight; primipara; physical condition excellent; the patient at full term. September 11th, 7 A.M., went into labor; pains were hard, but had little effect upon the cervix. The patient was brought to the delivery room at 11:15 P.M., September 12th, cervix gone and four and a half fingers dilated. September 13th, 12:39 A.M., cocaine gr. $\frac{1}{6}$ injected; 12:43 A.M., sensation delayed and diminished; 12:48 A.M., nausea and vomiting; sensation abolished; 12:53 A.M., profuse perspiration; 1:15 P.M., sensation returned for uterine contraction; 1:30 P.M., membranes were ruptured artificially, the patient unconscious of the procedure; 2:37 P.M., cocaine gr. $\frac{1}{6}$ injected; 2:45 P.M., nausea and vomiting; 2:50 P.M., forceps applied; traction at regular intervals painless; 3:05 P.M., first child born, vertex, three and seven-sixteenths pounds; 3:15 P.M., second child born, breech, two and eleven-sixteenths pounds; 3:25 P.M., placenta born; 3:50 P.M., sensation seems to be normal; 4:25 P.M., returned to ward. Post-partum temperature, 98 F.; pulse, 72; respiration, 24. The patient complains of headache; glonoin gr. $\frac{1}{30}$ given; 1 A.M., temperature, 100.6° F.; pulse, 84; respiration, 22. For twelve hours temperature remained about 100° F., and then fell to normal, where it has remained. In this case the headache was very pronounced, so that in all the patient received gr. $\frac{6}{100}$ of glonoin to stop the headache within twenty-four hours.

Case XII.—M. Y——, aged twenty; colored; curettage; admitted from another hospital to maternity five days after delivery. Temperature, 104° F.; foul, stinking uterine discharge. September 15th, 5 P.M., cocaine gr. $\frac{1}{4}$ injected; 5:10 P.M., sensation partially

abolished; 5:15 P.M., feels the tenaculum forceps on the cervix; 5:33 P.M., cocaine gr. $\frac{1}{6}$ injected; 5:38 P.M., sensation abolished; hand introduced and placental particles located; 5:48 P.M., curettage finished. Patient says she felt no pain or discomfort, nor was there any evidence that she did.

CASE XIII.—M. P——, aged twenty-eight; IIIpara; physical condition excellent; full term; went into labor at 11 A.M., September 18th; 11:45 A.M., brought to delivery room; cervix thinned out, and four fingers dilated; 12:25 P.M., cocaine gr. $\frac{1}{6}$ injected; 12:30 P.M., painful sensation abolished, complains of coldness of feet; 12:40 P.M., child born; mother heard it cry and exclaimed, "Thank God, and no pain"; 12:50 P.M., placenta born spontaneously without mother's knowledge; 1:30 P.M., patient carried to ward. Post-partum temperature, 99.2° F.; 5 P.M., temperature, 102.6° F.; pulse, 90; respiration, 24; 9 A.M. next morning. September 19th, normal; rest of convalescence normal—no headache, vomiting, or sweating.

CASE XIV.—L. R——, aged thirty-two; multipara; physical condition fair; five previous labors; fourth child delivered with instruments; went into labor 12:10 A.M., September 12th, position V. R. M. P.; membranes ruptured 3 A.M., September 12th; patient brought to delivery room at 7:30 A.M.; cervix fully dilated; 8:30 A.M., cocaine gr. $\frac{1}{6}$ injected; 8:36 A.M., patient nauseated and vomiting; 8:38 A.M., sensation to pain abolished below nipples; 9:34 A.M., still feels uterine contractions, but does not notice pin-prick; 9:30 A.M., pains have returned; 10:35 profuse perspiration for about one-half hour; 10:40 A.M., head shoved back above brim of pelvis and rotated into L. M. A.; 11 A.M., child spontaneously born without pain to mother; 11:20 A.M., placenta expressed by modified Credé method; 11:30 A.M., patient carried to ward. Post-partum temperature, 99.4° F.; pulse, 74; respiration, 28; 12:05 P.M., patient vomited; 1 P.M., temperature, 100° F.; pulse, 102; respiration, 16; complains of pain in back and head; 9 P.M., temperature, 100.2° F.; pulse, 80; respiration, 18; severe headache. Glonoin gr. $\frac{1}{50}$ given and headache ceased after an hour. September 13th, 9 A.M., temperature, 98.4 F.; pulse, 72; respiration, 18. Temperature has been normal up to time of discharge from hospital.

CASE XV.—M. H——, aged twenty. First full-term child; had a miscarriage at four months, eighteen months before; physical condition good; highly neurotic. September 11th, 7 A.M., went into labor; pains fair; cervix admits tip of finger; vertex L. O. A. September 12th, 10:45 A.M., the patient was brought to delivery room; cervix three and a half fingers dilated and thinning out; head partly engaged; 11:30 A.M., September 12th, cocaine gr. $\frac{1}{3}$, morphine gr. $\frac{1}{20}$ were injected into spinal canal; 11:37 A.M., sensation to pin-prick gone; muscles tonically contracting. Uterine pains still felt; 11:45 A.M., total abolition of pain sensation below nipples; uterine contraction not felt; 12:04 P.M., marked tonic contractions of leg muscles; 12:34 P.M., profuse perspiration. Says that for the last ten minutes things have looked red before her eyes; 1:12 P.M., pain to pin-prick felt, but uterine contractions give none; 1:40 and 1:50 P.M., patient vomited; 2 P.M., feels the contractions of uterus; 2:28 P.M., cocaine gr. $\frac{1}{6}$ injected with no further result; 2:49 P.M., cocaine gr. $\frac{1}{6}$ repeated; 3:02 P.M., forceps applied and patient complains severely of the tractions alone, but has no pain; 3:13 P.M., child born; no pain. There was some doubt in the minds of the gentlemen present whether the narcosis was successful, as the patient yelled at the top of her voice when the necessarily powerful tractions were made. To my mind, the patient, seeing all the manipulations as they were done, was simply fearful of our giving her pain, and anticipating this pain simply gave vent to her feeling, for fear of realizing what never was felt by her. To prove that she really did not suffer, the forceps was removed; a natural pain occurred of which she was absolutely unconsious, and on command she began to bear down, so that the head was forced well down into view of those around her. Again, when the perineum was absolutely distended, the house surgeon held the head fixed at this point for fully two minutes, and yet when under other normal condition the acme of suffering is reached, this patient lay perfectly quiet, absolutely free from all pain or discomfort. After the labor, when the patient's mind was clear, and her nervous condition quieted, she admitted total absence of pain. 3:18 P.M., placenta removed manually; 3:35 P.M., the patient returned to ward. Post-partum temperature, 100.6° F.; pulse, 100; respiration, 32; 7:30 P.M., profuse perspiration and severe headache; 10 P.M., glonoin gr. $\frac{1}{100}$ was given. The temperature stayed about 100° F. until 5 P.M., next day, when it dropped to normal and remained there.

CASE XVI.—L. S——, aged thirty-one; multipara; previous labor normal; has mitral regurgitant murmur. Presentation vertex, position R. O. A. The patient went into labor August 25th, at 4 A.M.; pains poor; cervix admits tip of one finger. At 1 P.M., patient was brought to delivery room, four fingers dilated and cervix thinned out completely; 1:33 P.M., cocaine gr. $\frac{1}{3}$ injected into spinal canal; 1:34 P.M., pulse, 90; 1:35 P.M., sensation to pin-prick and pinching below umbilicus gone; 1:43 P.M., patient vomited; 1:45 P.M., pulse, 118; 1:46 P.M., version, and baby delivered without pain to mother; 1:46 P.M., pulse, 92. Placenta removed manually without pain to mother; 1:51 P.M., slight nausea and vomiting. Pulse, 94; 1:54 P.M., patient is beginning to perspire; Pupils moderately dilated and react well to light and on accommodation; 1:57 P.M., marked perspiration; pulse, 88; 2:10 P.M., suture of cervix gives no pain to patient; 2:35 P.M., vomited; 2:40 P.M., patient taken to ward; no pain. Post-partum temperature, 98.6 F., pulse, 66; respiration, 18. August 25th, 1:30 A.M., temperature, 100.4° F.; pulse, 80; respiration, 22; she has had headache; glonoin gr. $\frac{1}{100}$ stopped it; 9 A.M., temperature 99.2° F., and remained normal.

CASE XVII.—B. E——, aged twenty-nine; physical condition poor at term. August 22d, at 7 P.M., patient went into labor; pains strong and occurring every half-hour. Presentation vertex; position, L. O. A. At 11 A.M., August 23d, patient was brought to delivery room: cervix gone, and four fingers dilated; pains strong every two minutes; 11:30 A.M., eucaine gr. $\frac{1}{3}$ injected; 11:35 A.M., patient vomited; 11:45 A.M., no anæsthesia obtained; 12:45 P.M., eucaine gr. $\frac{1}{3}$ injected; 12:50 P.M., the patient vomited and complained of cramps in lower extremities; 1 P.M., anæsthesia below umbilicus; uterine contractions not felt; 1:15 P.M., sensation is returning for pin-prick, and there is slight knowledge of uterine contractions; 1:25 P.M., pains are severe; 1:35 P.M., child born, and during the last uterine contractions the pain was normal; 2:15 P.M., the patient in ward. Post-partum temperature, 98° F.; pulse, 60; respiration, 28; 3 P.M., complains of headache and thirst; 5 P.M., temperature, 101° F.; pulse, 80; respiration, 20. The patient is in profuse sweat; headache severe, heavy feeling in legs; 10:20 P.M., glonoin gr. $\frac{1}{100}$, morphine sulphate gr. $\frac{1}{4}$ given hypodermically; 1:45 A.M., August 24th, glonoin gr. $\frac{1}{100}$ given by mouth; 5 A.M., temperature, 99.4° F.; pulse, 78; respiration, 24. No headache after this; temperature remained normal, and rest of convalescence was normal.

CASE XVIII.—K. G——, aged twenty-one; primipara; physical condition excellent. The patient went into labor September 13th, at 11 P.M., pains good and

strong, and occurring every twenty minutes; patient was brought to delivery room at 9:30 A.M., September 14th, cervix gone and four fingers dilated; 10:14 A.M., cocaine gr. $\frac{1}{3}$ injected; 10:18 A.M., sensation to pin-prick gone in perineum and lower extremities; 10:19 A.M., no longer perceived uterine contractions; 10:20 A.M., the patient is quiet and no longer complains of pain; 11 A.M., child born, no painful sensations; 11:05 A.M., perineum sutured, no discomfort to mother; 11:15 A.M., placenta delivered without pain to mother by modified Credé; 11:30 A.M., the patient returned to the ward. Post-partum temperature 97.8° F.; pulse, 60; respiration, 22. The patient seems slightly exhausted; 2:15 P.M., complains of headache, which became severe at 3:20 P.M.; 4:45 P.M., glonoin gr. $\frac{1}{100}$ with relief; 5 P.M., temperature, 101.4° F.; pulse, 96; respiration, 26; 1 A.M., September 15th, temperature, 99.4° F.; pulse, 84; respiration, 22. Since then there have been no rise of temperature and no further headache.

Case XIX.—M. B——, aged twenty; primipara; physical condition poor. Patient went into labor at midnight of September 15th; the uterine contractions were poor and irregular. Presentation, vertex; position, R. O. A. September 16th, 8 A.M., the patient is having labor pains every three minutes, but not very severe; pain in back moderate; position, V. R. O. A.; 8:14 A.M., cocaine gr. $\frac{1}{4}$ per spinal canal administered. At this time pains were quite severe; 8:20 A.M., pain sensation in the right side gone, slightly dulled in left leg and thigh; 8:23 A.M., analgesia complete below nipples; 8:32 A.M., patient pale and nauseated; 8:35 A.M., is shivering but says she is not cold. Temperature, 98.2° F.; pulse, 124; respiration, 20; 8:50 A.M., the patient is still shaking; ability to distinguish between heat and cold absent in lower extremities; this is not so on the abdomen, arms, or face; 9:10 A.M., uterine contractions not felt; 9:11 A.M., membranes rupture spontaneously; the patient thought she was micturating; 9:30 A.M., has consciousness of uterine contractions; 9:56 A.M., cocaine gr. $\frac{1}{8}$ injected; 10.05 A.M., pain abolished; 10:20 A.M., forceps is applied; 10:29 A.M., episiotomy; 10:30 A.M., child born, no pain; 10:37 A.M., placenta born by expression; 10:45 A.M., perineorrhaphy; 5 P.M., September 16th, temperature was 101.2° F.; pulse, 88; respiration, 20. September 17th, 5 A.M., temperature normal; pulse, 88; respiration, 22. Rest of convalescence was uneventful.

Case XX.—L. S——, negress, aged twenty-six; primipara; physical condition excellent; at full term. At 10:30 P.M., August 27th, the patient went into labor. Presentation vertex; position, L. O. A. Pains infrequent and poor; before the injection of the cocaine the patient was crawling over the floor and shrieking with pain. August 28th, at 6:54 A.M., cocaine gr. $\frac{1}{3}$ was injected; 6:59 A.M., sensation to pain diminished in feet, legs, and thighs; 7:04 A.M., nausea and vomiting; 7:12 A.M., membranes ruptured artificially; 7:18 A.M., the patient in profuse perspiration; uterine contractions still keeping up rhythmically; 8:16 A.M., the uterine contractions are more frequent, and during them the patient is told to bear down, and in so doing experiences no discomfort; 9 A.M., low forceps was attempted, but the pains have returned, and so operations were suspended, and 9:16 A.M. cocaine gr. $\frac{1}{8}$ injected; 9:24 A.M., pains have gone and forceps is now applied; 9:30 A.M., child born without knowledge of the mother; 9:33 A.M., placenta born spontaneously and no pain; 10:20 A.M., patient returned to ward. Post-partum temperature, 98° F.; pulse, 90; respiration, 20; 2:10 P.M., patient complains of headache; ice bag gives relief; 5 P.M., temperature, 100.6° F.; pulse, 104; respiration, 20; 9 P.M., temperature, 100.2° F.; pulse, 100; respiration, 24; she complains of headache. August 28th, 9 A.M., temperature, 98.2° F.; pulse, 92; respiration, 20; no headache. Rest of convalescence was normal.

Case XXI.—M. W——, aged twenty-three; primipara; physical condition good; came to delivery room at 2 A.M., September 21st, cervix three fingers dilated and thinned out. At 2:21 A.M., cocaine gr. $\frac{1}{3}$ injected; 2:24 A.M., the patient vomited; 2:25 A.M., does not feel pin-prick below the nipples, nor is she aware of the uterine contractions; 2:40 A.M., the patient complains of great heat and is perspiring; 2:50 A.M., an enema was given with no discomfort to the patient; 3:20 A.M., uterine contractions begin to give pain; 4:07 A.M., cocaine gr. $\frac{1}{6}$ injected; 4:16 A.M., absolute analgesia; the patient is vomiting at 4:36 A.M.; 5:30 A.M., child is born, some slight pain; 5:10 A.M., perineum sutured; 5:24 A.M., placenta delivered with slight pain; 6:14 A.M., the patient is carried to ward. Post-partum temperature, 99° F.; pulse, 80; respiration, 36; 7 A.M., vomited; 9 A.M., temperature, 100.6° F.; pulse, 68; respiration, 36; 9 P.M., temperature, 99.4° F.; pulse, 80; respiration, 26. September 22d, temperature, 98.4° F.; pulse, 80; respiration, 20. N. B.: This patient never had the slightest headache, and has been perfectly comfortable during her convalescence.

Case XXII.—R. B——, aged twenty-two; primipara; is in secondary stage of syphilis. The patient is in the ninth lunar month and has not felt child move for the last week; fœtal heart not heard. The patient went into labor at 8 A.M., September 22d, pains poor and infrequent; at 11:30 P.M., patient was brought to delivery room with very hard pains; cervix three-fourths dilated and thinned out almost completely; 12:18 A.M., September 23d, cocaine gr. $\frac{1}{4}$ injected; 12:22 A.M., the patient still feels the contractions but to a lessened degree; 12:24 A.M., uterine contractions still less felt; 12:45 A.M., slight pain above symphysis pubis during contractions; 12:47 A.M., sensation to pain below nipples absent; 1:15 P.M., the patient is beginning to have severe pain during uterine contraction; 2:18 P.M., cocaine gr. $\frac{1}{4}$ again injected; 2:57 P.M., forceps applied without the patient's knowledge; 4:04 P.M., macerated fœtus born, without pain to mother; 4:15 P.M., placenta born spontaneously; 4:20 P.M., perineal tear sutured without pain to mother. Post-partum temperature, 99.2° F.; pulse, 88; respiration, 24; 6:10 P.M., the patient has headache; 11 P.M., hyoscine hydrobromate gr. $\frac{1}{150}$ given; headache gone in twenty minutes. The twenty hours are not up at the report of this case, so that the temperature curve cannot be noted.

Case XXIII.—H. S——, aged twenty-two; primipara. September 23d, at 9:29 P.M., cocaine (lumbar puncture) gr. $\frac{1}{3}$; external os two fingers dilated; cervix almost gone. Uterine contractions every three minutes; 9:35 P.M., sensation to pin-prick in lower extremities almost gone. Vaginal examination, which before lumbar puncture gave great pain, now causes no discomfort; manual dilatation of cervix, no pain; 9:55 P.M., pains in back have returned; 10:15 P.M., cocaine gr. $\frac{1}{4}$ injected; 10:18 P.M., sensibility to pain again totally abolished; 10:30 P.M., the patient vomited; 10:32 P.M., complains of great warmth and perspires profusely; 10:34 P.M., forceps applied without pain or knowledge of patient; 10:55 P.M., child born without pain, but during the tractions on the head there was some slight pain; 11:10 P.M., placenta born spontaneously with no pain; 11:25 P.M., perineum sutured with not much discomfort to the patient; patient carried to ward at 11:50 P.M. Following this delivery hyoscine hydrobromate gr. $\frac{1}{150}$ was given, and none of the usual after-symptoms came save a rise of one degree in temperature.

OBSERVATIONS ON SUBCLAVIAN DELIGATION.*

BY SCHUYLER COLFAX GRAVES, M.D.,
GRAND RAPIDS, MICH.

WHILE the operation of placing a ligature around the subclavian artery is not a common one and hence has no everyday bearing upon the profession, it nevertheless is a most important procedure, and, as a rule, announces in the demand for its performance an urgent necessity. That the operation is anything but simple every operator of experience will admit, and therefore any contribution to the anatomy or surgery of this subject which will tend to diminish its perplexities, and thus render its performance easier, will add materially to our common stock and bear fruit in the curtailment of its present dangers.

The original guide to the third or operative portion of the subclavian artery was the scalenus anticus muscle, with the first-rib tubercle marking the site of its insertion, and these factors have retained their prominence in this respect to the present day.

FIG. 1.—Boundaries of the New Triangle: Cord of the brachial plexus externally; scalenus anticus muscle internally; first rib inferiorly. 1, Sternomastoid muscle; 2, 3, divided portions of the posterior belly of the omohyoid muscle; 4, scalenus anticus muscle; 5, cord of the brachial plexus; 6, scalenus medius muscle; 7, subclavian artery; 8, first rib; 9, subclavian vein.

That the exposure of these landmarks is a delicate feat in itself no one will gainsay. The scalenus anticus lies deeply in the neck and bears an intimate relation to such important structures as the subclavian vein, the phrenic nerve, the thoracic duct, the pleural apex, etc., not mentioning the artery under consideration and its branches. In fact, the thorough, workmanlike exposure of this anatomical guide constitutes the principal and most dangerous feature of subclavian deligation.

In my own experience, limited to one case on the living subject, but including many dissections and post-mortem operations, the truth of the foregoing has been brought forcibly to my mind; but I early saw what I then believed would prove to be an easier and as constant a guide to the artery as the scalenus anticus. I refer to the cord of the brachial plexus.

The plexus in its relation to the subclavian artery is not spread out and loosely arranged, but is round, compact, and invested with a special fascia, so that by the novice it can readily be mistaken for the anterior scalene muscle. As a matter of fact, the tendinous expansion of this muscle above its point of attachment to the first rib bears a striking resemblance to the white, corded nerve-trunk as seen through its fibrous investment. The inexpert, seeing and feeling the cord, can thus easily imagine that he has exposed the muscular guide, and hence be thrown completely off the track.

Speaking of the brachial plexus, Gray,[1] in this connection, says: "It is broad and presents little of a plexiform arrangement at its commencement, *is narrow opposite the clavicle* [italics mine], and becomes broad and forms a more dense interlacement in the axilla." This narrow portion is the new guide, and is the structure previously described as round and compact and as bearing so close a resemblance to the old muscular guide.

I desire to call the attention of the profession to two facts in connection with this subject:

1. The brachial-plexus cord is an easier guide than the anterior scalene muscle to the subclavian artery.

2. This nerve bundle is as reliable, is as constant a factor as the latter.

Kocher[2] says: "The relation of the artery to the nerve plexus is very characteristic."

The mere statement of the liability of error in mistaking the cord for the muscle proves the existence of the first of these facts, and for convincing evidence as to the truthfulness of the second I recommend to my hearers the scalpel and frequent visits to the dead-room.

If this recommendation be adopted not only will the constancy of the cord as a guide factor be established, but the investigator will also notice that the artery lies considerably higher in the neck than does its companion vein, this difference in altitude being more pronounced on the left side than on the right.

Some authors seem to think that the brachial cord is more difficult to expose, because of its imagined depth, than the anterior scalene muscle. This is not so. The easily and, I believe, oft made error of mistaking the cord for the muscle demonstrates the relative superficiality of the former. Moreover, my personal dissections as well as my operative experience confirm this statement, and eminent practical surgeons bear corroborative testimony as follows: Liston:[3] "You get at the nerves and expose them distinctly enough, and a little lower down on the same plane you at least reach the vessel." Agnew:[4] "If the cords of the brachial plexus or the omo-hyoid muscle are seen the exploration must be carried farther downward in the direction of the chest, and more inward, as the artery lies between the scalenus anticus muscle on the inside and the brachial plexus on the outside." Kocher:[5] "After removing the adipose tissue the thin, deep fascia covers the brachial plexus, now becoming visible, whose thick nerve trunks emerge between the scalene muscles and descend steeply under the clavicle."

It was with much interest and considerable pleasure that I noted, in my dissections, a clear-cut triangle which bears a constant relation to the third portion of the subclavian artery; in which, as a rule without exception save in case of gross irregularity, this portion of the artery will always be found. This triangle is

* A paper read before the Surgical Section of the Michigan State Medical Society at Mackinac Island, Mich., July 11, 1900.

located almost wholly below the posterior belly of the omo-hyoid, and hence is a component part of the subclavian cervical triangle. Its boundaries are as follows: externally, the cord of the brachial plexus; internally, the scalenus anticus muscle; inferiorly, the first rib. Within these boundaries the subclavian artery can always be found. It is an ultimate triangle, incapable of further subdivision, because its boundaries come into actual touch with the vessel, no other tissue intervening.

Treves[6] describes a triangle in connection with the subject of subclavian ligation. He says: "It [the subclavian artery] runs in a triangle, the base of which is formed by the outer edge of the anterior scalene and the sides by the clavicle and the omo-hyoid." This triangle varies but slightly from the subclavian triangle itself, the outer edge of the scalenus anticus being substituted for the corresponding edge of the sterno-mastoid, and it has no working value in the performance of the operation under consideration. The relative merit of the newly mentioned triangle and the one described by Mr. Treves I leave to the judgment of my audience.

The subclavian vein crosses this new triangle, if it cross it at all, low down, passing in front of the scalenus at its costal attachment, while most of the triangular interspace is occupied by the artery, particularly in its upper portion where the vessel will be found solitary. Reference to this condition of affairs has indirectly been made in the foregoing by the statement concerning the different cervical levels of the artery and vein. This solitary point in the course of the artery being the most superficial, the highest, and the least associated with important structures, is naturally the site of election in any operative attack upon the same.

In contradistinction to the exposure of the vessel at this point I need but mention the usual search for the first-rib tubercle, deeply situated in the neck and in relation to structures the accidental wounding of which might mean dire calamity to the unfortunate patient.

Moreover, the reliability and hence the real value of this guide is sadly shattered by no less distinguished an authority than Agnew,[7] who says: "This tubercle to which so much importance has been attached is, in my experience, not a very reliable guide in consequence of its development being very imperfect." The contrast between the deeply lying tubercle (which may or may not have an existence) and the brachial cord at the upper confines of the new triangle must make self-evident the superiority of the latter over the former, as a guide to the artery under discussion.

Now to the point of this paper. I propose substituting for a difficult guide in the ligation of the subclavian artery an easy one, viz., the cord of the brachial plexus of nerves for the scalenus anticus muscle.

In the performance of this operation, then, if, instead of exposing the deep-lying scalene muscle and feeling in front of it, the more easily located brachial cord is exposed and the finger placed behind it, less time will be consumed and fewer important structures endangered. The resultant, other things being equal, must be a shrinkage in the mortality rate.

The illustration is from a photograph of a personal dissection made for the purpose of elucidating the points I have here brought out.

TUBERCULOSIS AND ITS TREATMENT.[1]

By MARGARET STANTON, M.D.,

PRESIDENT OF THE ONONDAGA COUNTY MEDICAL SOCIETY.

It is safe to say that the burning medical question of the day is tuberculosis and its treatment. We are now in the closing years of the longest reign in British history; you know what of war and conquest that period embraces. Could the dead buried in those battles by land and sea, with those who afterward died of their wounds or from exposure or disease contracted in the service, rise in one great company, it would be far outnumbered by the dead from tuberculosis. The loss is not the less striking because unaccompanied by the boom of cannon, the clash of steel, the whiz of bullets, the click of telegraph wires, the speed of railways, or the big type of yellow journals. The masked, the insidious progress of the capture of the citadel of life by this all-conquering disease is marked with such delusive fair-seeming, that the tuberculous with his dying lips assures you he feels better, and is confident of recovery. War takes away our strongest and those in their prime, but this dread scourge makes of our strongest the weakest, and spares neither sex nor age.

I have lived the greater part of the last ten years among the tuberculous, and the study of the treatment of this disease has forced itself upon me. We have progressed so far in the study of the cause of the disease that we feel sure we have caught the culprit. We have declared it to be contagious, and, therefore, a menace to the public health—yet we have left it at large to prey upon the people because there is not sufficient public enlightenment to quarantine it properly. Fellow-practitioner, that is your fault and mine. We have not been doing our duty. We have been taking our work lightly. Is it that we have been careless or ignorant or commercial? There is war to be waged; there is to be brisk fighting all along the lines to the extermination of the germ or the patient. Let us prepare ourselves well, for the enemy's phalanxes are full and the patients must put up a great fight. But if it is true, whisper it not in Gath, "that the struggle must begin in the ranks of the profession itself; let it start at once and not cease until every old prejudice and ignorance are crushed to earth to rise no more." Our only chance is during the incipiency of the disease. Early diagnosis is all-important. It wins the day by reducing the number of the slain to a minimum. Even with improved methods of diagnosis we must often revert to the old, which existed before the discovery of the bacillus. Though the lungs give forth no sign and though the family and personal history be mute, when there is loss of flesh, appetite, and strength, loathing of fat and distress of digestion, with absence of symptoms of other diseases, remembering that the lungs hide away their secret as their depths are silently being undermined, that family history is often unreliable, and that tuberculosis frequently begins that way, let us treat our case as if it stood out clearly photographed. Having the case before us, the next move is taking those measures which will insure that which we call cure. To cure, what will cure? When death gives up life's secrets we know that nature cures sometimes; but her powers are not ours, and we cannot distil her elixirs.

I will illustrate by a case under my observation how

[1] Address of the president at the annual meeting of the Onondaga County (N. Y.) Medical Society.

physicians proceed to bring about cure. The patient was from one of the largest cities in this State, a young woman teacher twenty-four years old, well built, taking much exercise in the open air, passing her vacations with her brother in the woods fishing, tramping, bicycling, and taking long nights of sleep; she was out of sorts, nothing definite, food didn't taste good, bicyling was an exertion, walking a task, schoolroom duties were irksome. After a while of this the family physician was consulted, and recommended change of air, a visit to the Adirondacks, as a condition existed that might give rise to trouble in the lungs. This was scouted at home, no lung trouble ever having been known on either side. The family physician was getting old, they said, and the patient was advised to go to Dr. Blank, who was young, modern, had European advantages, etc. He declared there could be no degeneration in such finely developed lungs, laughingly remarked of the suggestion to go to the Adirondacks, "That will do no harm, but you need not go now; you can go a little while in the summer if you like" (yet six months); "torpid liver; don't mope nor worry, do this and take that." More valuable time passed without improvement. Once more to the doctor's, still another. This one had neither ifs nor ands. "Your lungs are in danger. Waste no more time with drugs. Go into pure air at once, and keep in it a year." When doctors disagree, who shall decide? I am not throwing stones, but is it too much to require unanimity in the treatment of tuberculosis? The meeting to discuss this entire subject, held at Berlin a year ago, did not settle this vexed question of treatment. There were differences of opinion, although the great majority favored the outdoor treatment. Pure air is the remedy; believe me, it is the whole thing. The purest air is to be sought for out-of-doors, and in the incipiency of the disease. This air may be found in different parts of the world, but I will confine myself to that part easiest of access to us, the Adirondacks of our own State. They may be reached from within the boundaries of this State in twenty-four hours. That is an inestimable advantage. The journey does not exhaust the patient's strength nor deplete his pocketbook. He can communicate with his friends quickly, and have their society when that seems a good measure. He may also have the hope and cheer of a visit from his family physician, if at any time it may seem advisable. He may even be permitted a few days at home when the craving for familiar scenes appears to stand in the way of improvement. Whether he goes to a sanatorium or not, certain rules must be followed. One of the most difficult things to be eradicated in the lines set down for a patient to follow is the belief in the necessity of exercise—exercise in every shape, from complicated gymnastics to record-breaking walks. We see the poor, deluded victims of a pernicious relic of barbarism every day on the streets literally walking to death. They exercise even in the second stage when they have "temperatures." Fancy a patient with typhoid fever or any other fever walking. It is left to their own judgment and discretion, too, when actually they have neither. The less left to their own determination the better. They are ill, and everything should be prescribed for them. The nourishment that should be used in building up the degenerate tissues of the body is wasted in harmful channels. Insist strongly upon this—no exercise whatever beyond lounging about to vary the position. It is pleasant and efficacious to be driven about at a moderate pace, kept without exertion in that finest of tonics, moving air, exhilarated and refreshed by changing scenery. This may be indulged in to the fullest extent in fine weather. Of course, when hemorrhage is to be feared, even the gentlest driving is not to be recommended. Mountain-climbing is a great temptation. It alone is responsible for a large increase in the death rate every year. Imbue your patients with such a wholesome fear of it at the start that they would consider it the wildest folly even to think of such a thing. The tuberculous patient must live to eat; he must be a feeder; his eating must be the object of constant care to himself and others. It is astonishing how much he can assimilate if he can only get it down.

One of my patients worked out a good rule for her own guidance which others will do well to follow: "I eat all I can of the dishes supplied for each meal; then when I can take no more I finish with several glasses of milk, sometimes with a raw egg in each." I have given the rule to others and find it works wonders. It never spoils the appetite for the next meal, and one can worry down fluids when it would be impossible to swallow solids. For those who can take but very small quantities of food at a time, lunches every two hours are desirable. Many patients require the most minute attention in the matter of food; the exact quantity must be insisted on with them. For lack of this insistence, I have seen them pass days with food scarcely enough to support an infant, yet thinking themselves indulging almost voraciously in the light of their poor appetites. The time when the patient's demijohn could not be emptied too quickly has gone by, I hope never to return. Yet the shadow of that belief still lingers, especially among the laity, and the patient must be fortified to refuse the drop of good whiskey or the sip of old brandy that is offered him for his good, and to turn a deaf ear to the histories of cures that stimulants have wrought. Patent medicines and cough mixtures will be urged upon him, and if weak or unwarned he may use them, to his detriment. Early retiring must be inculcated. There cannot be too much of nature's sweet restorer, balmy sleep. Exciting amusements between the last meal and bed-time, and also irritating arguments, are to be forbidden. Quiet conversation, light reading, etc., are the best pastimes. A dry rub or an alcohol or sea-salt bath every night is most excellent, the patient being his own rubber. Protected from draughts, he must sleep with windows well open, even in 30° below zero weather. When possible, in summer he should sleep in a tent, well floored. If he is confined to the house or bed an airy room must be selected, and all windows must be thrown open night and day. We should discourage requests for permission to go home, even for a few days. I have seen the work of months in the Adirondacks negatived by a week at home, and cases which might have resulted in cure go on to death from the same cause. You will be assailed by piteous appeals for a home visit, but you must firmly deny. Occasionally it is wise to grant the indulgence, but generally a kind letter stating the danger suffices. Patients, especially men, in the second stage should never be sent away alone. If they cannot have the company of a friend, a woman preferred, then a trained nurse should go. These lonely, unhappy creatures present the saddest sights. As in the end some one must be sent for, it is better to start with a care-taker, when care will not come too late for cure. For these unfortunates admonitions and precautions must be doubled, as this stage is one of despair. They do not yet appreciate their slow but sure gain. Patients in the third stage should never be encouraged to leave home. Their days are shortened in most cases, and disrepute is brought upon the treatment. Failures are remembered, while no account is kept of their causes.

Explain the danger that lurks in dried sputum. The handkerchief should never be used to receive it, but instead of this the individual cuspidor, squares of cheese-cloth, Japanese paper, absorbent cotton, or clean rags. These should be burned within twenty-

four hours. The enormity of promiscuous expectoration should be held up to general execration. Among the tuberculous will be found the usual percentage of those who "cheat the doctor," especially in the matter of remaining out-of-doors. Eight hours in winter, and ten in summer at least, should be spent in taking the cure. Dry summer evenings may be passed in the open air until nine o'clock. Time spent indoors does not count. Indoor air, about the same in all sections, is not fit to breathe. A temperature of 20° below zero in the open air in the Adirondacks does not seem so cold as zero weather here; it is wonderfully bracing. In it the hours pass quickly and pleasantly while one is out-of-doors, bundled up in furs. When exercise can be taken, walks in the forest, skating, and snowshoeing are delightful amusements. The encouragement of a fad is to be strongly urged—an out-of-door fad by all means. I have met tuberculous patients whose camera work was fine; and some added largely to their income by the sale of their pictures. A partnership in which one furnished the description for the newspapers and the other the photographs of places of interest in the mountains, interested me very much. The indulgence in a fad occupies the mind, preventing too much brooding and introspection. Time, next to air, plays the principal part in the cures—time, plenty of time. We say to a patient in the incipient stage: "In a year you will be cured." True, but not cured in his sense—to go back, pick up the thread of his life where he dropped, it and carry it on as he left it. His cure does not enable him to do that. In nine cases out of ten he pursues that course only to experience a renewal of his trouble. It requires from three to five years spent in the Adirondacks to make it safe for a man to marry and live anywhere. So when we say a year to these patients, it is with a reservation. Is it well to have that reservation? One might despair at the beginning if told that the treatment must be continued so long, who might be brought on to accept the limit in progressive stages from one year.

Now comes a consideration of those who from their own resources cannot hope to avail themselves of this or any other means of cure. What is to be done for them? The tuberculous patient without money or friends is the most pitiable creature on earth. Our heart's profoundest sympathy is his. Let us give him our very greatest aid. Let us hold up his misery and desolation, until the whole world recognizes them and joins in ameliorating his condition. In this age of altruism, we see philanthropy shedding its bounty with overflowing hands on every conceivable cause. Bibles for the Hottentots, clothes for the South Sea Islanders, churches for the millions, colleges for the different sects and sexes, libraries for the masses, hospitals for the maimed, the cancerous, and the epileptics, and every claim is answered, while the hosts of the tuberculous have not been offered a place where they may cough out their allotted three years in decent peace and comfort. And now that the government is becoming so paternal, what has the State done for the tuberculous? Nothing, I may say. Certainly nothing for them as a class. Their claims upon it have been met with scant recognition. To those having absolutely no other resource it has offered its poor-houses, which means death without reprieve in a very short time, and burial by the State. If the cost even of maintenance in the poor-house and of burial, with a trifle more, were used in a more judicious way, lives would be saved and good citizens spared to the State. Zola, in his last great work "Fécondité," makes a powerful appeal for larger families in France. At the present birth rate, he says, France will soon lose her rank as a great nation from sheer lack of numbers. If he would but enlist his masterly pen in the effort to keep in life those already born, his task would not be so formidable. The tuberculous poor are best cared for in sanatoria, and these should be built and maintained by the State. They should be absolutely free for those having no means whatever, and at a low fixed rate for those able to pay something. The sanatorium is an educator; in it a patient is taught how to get well, keep well, and preserve himself from being a source of danger to others. When he goes abroad he is capable of teaching self-care to others. The best model of a sanatorium on the cottage plan is to be found at Saranac Lake: a central building containing the offices of administration, common dining-room, reception and music rooms, with baths and infirmary; an amusement pavilion that may be opened on all sides to the weather, fitted with pool and billiard tables; a separate building for the library, golf, croquet, and tennis grounds. The cottages contain from six to eight light rooms opening upon a central common sitting-room, they are surrounded by verandas and are very cozy. A Catholic sisterhood maintains a similar one at Gabriels, N. Y. It has the advantage of being close to the railway station. The Berlin congress decided that sanatoria need not necessarily be in the mountains, but must be in the vicinity of forests. Each county can find an excellent site within its own border. Pompey Hill affords just the spot for Onondaga. Let this society make a foundation there its aim.

APPENDICITIS LARVATA AND INFLAMMATION OF THE RIGHT BROAD LIGAMENT, TUBE, AND OVARY.

By OTTO THIENHAUS, M.D.,

MILWAUKEE, WIS.,

FORMERLY DIRECTING PHYSICIAN OF THE WOMAN'S PRIVATE HOSPITAL, STENDAL, GERMANY.

At the twenty-eighth German Surgical Congress held at Berlin, in April, 1899, Ewald introduced the term appendicitis larvata. By this expression he understood appendicitis of a chronic, insidious character which moves softly without developing into a real attack of acute appendicitis. Such a conception would correspond to the actual situation and reveal the nature of the disturbance.

Not infrequently we meet in practice patients complaining of intermittent pain in the abdomen of varying degrees of severity, which disappears after a longer or shorter time. These cases are very often treated as intestinal colic, gastritis, or flatulent enteritis without or in connection with some sort of enteroptosis. On a careful examination of these patients pain may be elicited by palpation, sometimes at McBurney's point, sometimes in the neighborhood of the navel, or even in the left iliac region or beneath the liver; in some of these cases there are occasionally slight elevations of temperature.

In recent years, in which the study of the topographical anatomy, pathology, and symptomatology of the processus vermiformis has aroused the deepest interest and has resulted in the most exact investigations, it has also been shown that these vague pains may have their real origin in an anatomical lesion of the appendix. In some cases, in which it was believed that movable kidney or retroflexio uteri was the cause of the symptom complex, and in which, in order to overcome these disturbances, the kidney or the uterus was fixed, it has been found that these operations had no influence whatever upon the pain, and many operators have had to confess with Wood:[1] "I can attribute many of my early failures in abdominal work to not directing my attention to the appen-

[1] American Journal of Obstetrics, 1899, p. 94.

dix, the pain in the right side persisting as well as the gastro-intestinal disturbances."

Edebohls[1] has shown that movable kidneys are very often closely connected with appendicitis larvata, which he thinks is due to the pressure of the movable kidneys on the vena mesenterica superior causing hyperæmia in the processus. He even says that movable kidney which is not followed by appendicitis does not furnish an indication for treatment. This opinion is still very far from being generally accepted, as other authors have not been able to find any relation between these two disturbances. So far as my experience goes I must confess that in some cases this coincidence without doubt exists, and when we fix the kidney in such cases, without paying attention to the appendix, the patients will be in the same condition as before the operation. Upon a macroscopic and microscopic examination of the underlying anatomical causes of the above-named disturbances, it has been found that there is no proportionate relation between the anatomical conditions and the troubles presented by the patient. Sometimes it has been seen in the sectio in vivo that the serosa of the appendix was only slightly injected, generally at the tip; sometimes there have existed only delicate adhesions between the appendix and another portion of the bowel, or one of the pelvic organs, or the lateral abdominal peritoneum; and upon dissection of the processus there is frequently found only a slight catarrhal inflammation with swelling of the follicles of the mucosa, or sometimes a follicular abscess, sometimes stenosis at one or more points, sometimes slight fecal concretions. On the other hand, we all know of cases coming to post-mortem section, in which during life there were no or very few symptoms of disturbances, but in which were found surprising destructive lesions and malformations of the appendix. At this point I will call attention to cases cited by Combemale,[2] Guttman,[3] and Maryland,[4] in which the distal portion of the appendix was dilated into an egg-shaped, tense, cyst-like structure without giving rise to any subjective symptoms.

Wood[5] says that in nearly every recorded case of cystic disturbance of the vermiform appendix there were no subjective phenomena arising from the conditions, and that in the majority of cases the affection was discovered accidentally.

There seems to be some analogy between the condition of the processus vermiformis and gastric ulcer. Many pathological anatomists have stated that large cicatrices of former gastric ulcers are found in cases in which during life an examination would not have revealed any lesion of the stomach.

As the diagnosis of an appendicitis larvata, which at any moment may be followed by an acute attack of appendicitis, menacing life, is very difficult, I think every point which might suggest the possibility of such a condition should receive favorable consideration. In the following three cases, observed in my practice, there were symptoms of such a nature that it was possible, relying upon them, to make the diagnosis of appendicitis larvata:

Case I.—Miss O——, twenty-two years of age, complained for two years of vague pain in the abdomen, mostly in the right side; since the beginning of this pain she suffered from dysmenorrhœa, sometimes in combination with menorrhagia. Very often the pain extended to the epigastrium, the attack being followed by headache and slight rise of temperature, sometimes by diarrhœa. She thought the trouble was due to a blow on the abdomen. Since the beginning of her illness she had lost nearly fifteen pounds. At her first appearance I could not decide whether or not there was an hysterical element, though the family history on this point was negative. Examining the patient, I found by abdominal palpation slight tenderness upon pressure in the region of McBurney's point; no sign of exudate; hymen intact, but so distensible that it permitted the careful introduction of the index finger. There were no indications of gonorrhœa. On bimanual palpation I found the right tube and ovary very tender and slightly enlarged; the right broad ligament was retracted; the uterus was in dextro-retroposition; from the right ligament extending to the cæcal region there was a not well-defined resistance, which gave the impression of a structure of about the size of a lead pencil. My diagnosis was appendicitis larvata; the appendix extending to the small pelvis and perhaps adherent with the tube, retraction of the right broad ligament, inflammation of the right tube and ovary, dextro-retroposition of the uterus. At the operation (Sonnburg's oblique incision in the region of the anterior spine), which was kindly performed by Professor Rotter, of Berlin, who, seeing the case for the first time, was somewhat loath to believe the appendix was the cause of the trouble, the diagnosis was confirmed. The appendix removed was about 10 cm. long; upon opening it we found three constrictions with two fecal concretions, one at the tip of the appendix, the other between the two constrictions; the patient made an uneventful recovery, her weight increasing twenty pounds in two and one-half months. The dysmenorrhœa disappeared.

Case II.—Miss L——, twenty-three years of age, from a healthy family, complained of running pain over the abdomen mostly in the umbilical region. This condition in a more or less pronounced state had existed for some eight weeks, interrupted sometimes by constipation, sometimes by diarrhœa. The last menstruation had been very painful. The patient had been treated for some time on the diagnosis of enteritis catarrhalis. The examination showed tenderness on palpation near the navel on the right side; no sign of exudate; hymen intact. Rectal bimanual examination revealed the uterus lying in dextro-retroversion position, the right broad ligament shortened, and slight tenderness of the right adnexa. When I performed the operation I found the uterus lying as above mentioned; the tip of the processus vermiformis, whose serosa was slightly injected, with an appendix epiploicus originating from it, was attached to the right ovary by adhesions. I removed the appendix and fixed the uterus to the abdominal wall, after the method of Czerny-Leopold. The dissection of the appendix showed only swelling of the mucous membrane and follicles, the distal part of the process containing fluid fecal matter.

Case III.—Martha P——, nurse in my private hospital, twenty-eight years of age, complained for two years and a half of pain in the right inguinal region sometimes in connection with very painful menstruation. Since the beginning of her illness she never felt quite well and could scarcely perform her usual work. Six months ago she had to remain in bed six weeks suffering from intermittent fever and great disturbances in the abdomen, and was treated by Dr. P——, of Frankfort-on-the-Oder, Germany. Examining her, I found great tenderness on palpation at McBurney's point; no exudate; hymen intact; no sign of gonorrhœa; on bimanual palpation I found the right broad ligament retracted; the right tube enlarged at its distal end, the size of a hen's egg; the ovary on the same side the size of a small apple adherent to the tube, and very painful on palpation; the uterus in

[4] Transactions of the Glasgow Pathological and Clinical Society, vol. iv., p. 111.
[5] American Journal of Obstetrics.

retroflexion position; an adhesion from the ovary to the cæcal region could not be palpated; the adnexa on the left side showed no abnormal condition. Diagnosis: Appendicitis larvata, hydrosalpinx or pyosalpinx dextra, retroflexio uteri, oöphoritis dextra. Performing appendectomy, oöphorectomy, and salpingectomy, and dextraventrofixation of the uterus, I found the processus adherent to the fimbriated extremity of the tube, and the other complications as mentioned. The recovery was uncomplicated. A fortnight after the operation the patient was able to chloroform another of my patients for operation, and in a letter received half a year afterward she assured me that she was quite healthy and able to perform any required work. The dysmenorrhœa had not recurred.

If the symptoms found in these three cases are summarized, the following of a more general nature are obtained: Disturbances in the intestinal tract, flatulent colic, abdominal pain of more or less intermittent nature, located by the patient sometimes in the right, sometimes in the left iliac region, extending in some cases to the navel, epigastrium, or right hypochondrium. These disturbances are associated sometimes with headaches, dysmenorrhœa combined with menorrhagia, and more or less increasing cachexia; slight attacks of fever occur in some cases. On physical examination slight ill-defined tenderness is found at McBurney's point, about the navel, even sometimes in the left side or in the neighborhood of the liver. On bimanual palpation, through either the vagina or the rectum, the uterus is found to be in dextroposition, or dextro-retroverted or flexed, the right broad ligament shortened and retracted; the right tube and ovary more or less in a state of inflammation. In one case I was able to distinguish a structure of the configuration of the processus vermiformis with adhesions.

The question which should arise in a diagnosis of any abdominal inflammatory process in a woman is the possibility of the existence of hysteria. It is well known how difficult it is generally to exclude hysteria in cases of abdominal disturbance, mostly in those cases in which there is paralysis of the intestines, and the literature contains reports of cases in which a disregard of possible hysteria has led surgeons to perform laparotomy not only once, but even three times on one patient without finding an anatomical basis of the trouble. Nothnagel calls this condition pseudoperitonitis or pseudo-perityphlitis hysterica. I shall never forget one case in which the abdominal symptoms combined with the general condition of the patient misled Dr. Madgeburg (first assistant to von Bergmann's clinic in Berlin) and myself to a diagnosis of peritonitis, possibly of appendicular origin. It was shown by von Bergmann after chloroforming the patient, during which the bowels collapsed, that the whole symptomatology was due to hysteria, excited by a very slight attack of gall-stone colic. Of course an operation was unnecessary.

When the above-mentioned conditions of the pelvic organs are discovered in a female patient, the second most important and difficult question that arises, after excluding hysteria, is to determine whether this inflammation of the right side—tube, ovary, and broad ligaments—has its origin in an ascending inflammation, brought there by way of the vagina, or in a descending inflammation originating in the appendix, it being assumed that inflammations having their origin in other abdominal parts can be excluded. Probably the most common cause of inflammation of the tubes and ovary is the gonococcus, and the question of the existence of gonorrhœa must be settled before other causes can be considered. When it is found, as in the cases cited, that the patient shows no evidence of an earlier urethritis, no redness surrounding the region of the outlet of the Bartholinian glands, no sign of catarrh of the vagina and cervix, and when the inflammation is limited to only one side of the pelvis—as it is well known that gonorrhœa is prone to be bilateral—then another cause may be taken into consideration. It has been shown in recent years that contraction of the right broad ligament in connection with inflammation of the right tube and ovary, sometimes with dextro-retroversion or flexion of the uterus, points to an appendicular origin of the trouble. The diagnosis may be rendered still more probable by the already-mentioned general disturbances of the abdomen, and confirmed when one is able to palpate alterations of the processus, and to recognize adhesions between it and the pelvic organs.

It has been shown by many observers that appendicitis is more common in males than in females (McBurney states in the "International Text-Book of Surgery," p. 399, that the ratio is about four to one), and one thinks the reason for that is that the appendix in the female receives additional blood supply from the artery appendiculo-ovarica running through the ligamentum appendiculo-ovaricum. For the same reason it is said that appendicitis gangræ-nosa occurs less often in females. Through the lymphatics of this ligament, bacteria, it is believed, may wander from the appendix to the broad ligament and tube, causing inflammation of the latter. The existence of this ligament has been demonstrated by Fowler and Waldeyer. Of late it has been the subject of a great deal of discussion, and among others Barnsby[1] has denied its presence and believes that the bacteria are transported through adhesions between the organs. This was, I believe, the fact in the cases above reported, in which the inflammation of the appendix had caused adhesions between it and the right tube and ovary.

Of course adhesions between these organs can be developed only in those cases in which the appendix is rather long, gravitating by its own weight into the small pelvis, or in which there is a long mesocæcum or even no mesocæcum, but instead of it a mesenterium ileocæcale commune. The latter condition allows for the greatest mobility and dislocation of the cæcum, together with the appendix, and makes the recognition of inflammation of such a dislocated organ sometimes not only difficult but impossible, because it can, when lying for example in the left iliac region, produce inflammation and adhesions with only the left adnexa, or in other cases with the gall bladder and liver. Von Manteuffel has shown[2] that this condition can be a cause of volvulus of the cæcum followed by peritonitis, and that has to be taken into consideration when the question arises whether or not there is a peritonitis following volvulus or a peritonitis which had its origin in the appendix.

Another question which I would like to propose at this point is: Can the bacteria which are usually found in inflammation of the appendix (streptococcus, staphylococcus, and bacterium coli), when transported by way of the lymphatics or adhesions to the tube, give rise to suppuration of the normal mucous membrane of the tube? This question arises in connection with my last case, in which there was a hydrosalpinx, and it is believed that hydrosalpinx may result from an earlier pyosalpinx. Other authors deny this possibility (*vide* Veit's "Handbuch der Gynäkologie," p. 702). But it has been shown that the patient had intermittent septic fever lasting six weeks, some six months before the operation, and I think this was due to an existing pyosalpinx originating from the appendix. This question arose also in a discussion of a paper by Fueth, "Ueber Erkrankung des Processus

[1] Revue de gynécol. et de chir. abdom., 1898.
[2] Sammlung klinischer Vorträge, No. 260.

vermiformis und der Adnexe," [1] when Zweifel of Leipsic objected to the possibility of streptococcus, staphylococcus, and bacterium coli being able to excite pyosalpinx in the presence of an uninjured mucous membrane of the tube. Fueth thought it possible, but whether or not this can be accepted remains for more exact demonstration. This condition has, of course, nothing to do with those cases in which an abscess, originating from the appendix, breaks through into a tube and causes pyosalpinx.

Concerning the treatment of appendicitis larvata, it must be recognized that only operative measures can be taken into consideration. They are indicated because (1) there is no other means of correcting the existing pathological conditions, and (2) the patient is in constant danger of an attack of appendicitis followed by peritonitis. Barnsby, already mentioned, says that when the tip of the appendix is adherent to some abdominal organ with or without vascularization of its peritoneal serosa, there is absolute indication for operations. Furthermore, in young female patients one has to deal with the possibility of a subsequent pregnancy, and, as we all know that appendicitis in combination with pregnancy gives the most serious prognosis both for the fœtus (abortion is practically inevitable) and for the mother,[2] it is the physician's duty to explain to the patient the above-mentioned complication and to resort to radical treatment, that is, to operation.

Eleventh and Wells Streets.

Lupus Treated by Excision.—E. Lang gives the results of eighty-five cases of this disease, in which the affected portions of skin were excised and the defect covered by a plastic operation. Of this number thirty-nine are for various reasons not available for statistics, but the forty-six remaining have been free from recurrence for periods varying from one to seven years. Most of these had already for years been subjected to skilful medical treatment without permanent improvement, and in view of the absolutely positive results obtainable by surgical intervention the author strongly advises the measure in all cases in which a sufficiently radical operation can be done.—*Klinisch-therapeutische Wochenschrift*, August 19, 1900.

The Connection between Gastric and Uterine Disorders.—Ödön Tuszkai has made a careful study of the anatomical and other factors subtending the well-known reciprocal relationships of stomach and uterus. The connection between the two is intimate and far-reaching, but care is necessary to exclude disorders which simply chance to affect coincidentally both organs without being in any way interdependent. Three main channels of mutual influence lie open, through the nervous system, the circulation, and abnormal static relations. Of these the first is the most important, and the author differs from the usually accepted belief in placing the genital centre not in the brain or spinal cord but in the sympathetic system, its abdominal centre being not in the lumbar cord but in the solar ganglion. This, by means of the inferior hypogastric, the solar, and spermatic plexuses, establishes the reflex track between the uterus and the gastric branches of the vagus. Another more indirect route lies through the communications of the vagus with the sympathetic system through the utero-vaginal plexus and the para-uterine ganglia. In addition to the ligamentous and structural attachments of both organs intra-abdominal pressure plays a large part in maintaining their normal positions. Thus, under ordinary conditions this force strikes the uterus posteriorly near the fundus, keeping it normally anteflexed, but when the static equilibrium is disturbed or destroyed in consequence of gastric dilatation, gastroptosis, etc., the axis of pressure may run directly through the fundus and induce a downward displacement, or lie still farther forward and produce a retroversion. While chemical and endozymotic influences may travel through the blood current and so effect reciprocal gastric and uterine changes, this channel is of less importance than the other two.—*Monatsschrift für Geburtshülfe und Gynäkologie*, August, 1900.

Inflammation of the Middle Ear in Infants and Children.—A. O. Pfingst says middle-ear involvement is particularly noticeable in measles. Jobeitz believes it is affected in every case. The Eustachian tube in children is wider and gives a better passage to infections from the naso-pharynx. The benign course is characteristic of otitis in early life, and pain is not so pronounced a symptom as in the adult. Spontaneous rupture of the drum is also not so common. The tendency for the inflammation to spread to the mastoid cells is not so great, and operative intervention is less often called for. The suggestion of Barth to examine the ears of all sick children several times during their illness is a good one. At the first sign of retained pus or of extension of the inflammation to the mastoid cells paracentesis should be done. The incision should be kept open as long as acute symptoms are present. This is best done by applying a crystal of chromic acid to the cut edges. Whenever the symptoms of mastoid involvement are pronounced or persistent the mastoid must be opened. Fortunately, a small opening suffices in babies.—*The American Practitioner and News*, August 1, 1900.

Legal and Medical Insanity; Reflections upon the Recent Trial and Conviction of Bradford P. Knight at Augusta, Me.—C. P. Bancroft states that the judge in his charge to the jury acknowledged that the murderer might be insane, but that his mental disease might not have progressed to this particular point of destroying a knowledge of right and wrong with reference to the particular act. The author says that, in point of fact, insanity and irresponsibility, or at least modified responsibility, are nearly if not quite synonymous. The real test of responsibility is not a knowledge of right and wrong with reference to the particular act, but as Dr. C. F. Macdonald has expressed it, "knowing the right and knowing the wrong, has the man the power to choose the right and avoid the wrong?" It is not a question of knowledge, but of power to choose between two courses of action. If he has not such power, then his act is the product of his disease, and he is not responsible. Chief Justice Doe's ruling in a famous case was that there is no legal test of insanity, but that each case must be decided on its own merits; that insanity is a mental disease; the product of mental disease cannot be a crime; tests of mental disease are matters of fact, and whether the defendant has a mental disease, and whether his act is the product of that disease, are questions of fact for the jury to decide. This is good law and sound medicine.—*American Journal of Insanity*, July, 1900.

Further Laboratory Studies on Uric Acid in Neurasthenia, and on Auto-intoxication in Nervous Disease.—F. Savary Pearce concludes from experimentation and observation that we have sufficient data to say positively that neurasthenic conditions are associated with the circulation of such an irritant as uric acid in the blood. The physiological absorption of proteids is inhibited in an irregular fashion in the

[1] Centralblatt für Gynäkologie, 1899, p. 17.

[2] Hlawacek (Monatsschrift für Geburtshilfe und Gynäkologie, 1897, Bd. vi., Hft. 4) reports thirteen cases of pregnancy complicated with appendicitis, eleven of which resulted in death.

neurasthenic subject, or else the condition is due to want of proper vasomotor control of the capillary blood-vessels, thus permitting an irregular and improper elimination of uric acid, etc. It must needs be that in such central disease the central energizing influence (of the neuronic vitality *per se*) is greatly enfeebled, and is unable to carry this weakened vital action through the nerves to the organs of digestion and absorption. This vicious cycle of disturbed metabolism being established, we have secondary irritations continuously operating on the already devitalized nerve centres. The sympathetic also becomes over-excited, and in a condition of irritable weakness as manifested in the resultant symptomatology of neurasthenia.—*The American Journal of Insanity*, July, 1900.

The Effects of Migration from the Northern to the Southern Hemisphere.—R. Humphrey Martin, who has practised medicine in Australia for twelve years after a previous experience in England, gives an entertaining comparison of the people met with in the two latitudes. Concerning matters purely medical he notes in the southern hemisphere, Australia especially, the prevalence of hydatids, the absence of rickets, the relative infrequency of post-diphtheritic paralysis, the great mortality of typhoid, particularly that variety known as "gold-fields" fever, and the fact that pulmonary tuberculosis is only about one-half as frequent as in the northern hemisphere. Measles is about as severe, while scarlatina is much milder.—*Australasian Medical Gazette*, July 20, 1900.

The Pathogenesis of Flat-Foot in Cases of Varicose Veins.—Eriberto Aievoli holds that flat-foot is a result of the varicose condition, the cause being found in the nutritive disturbances induced by the perturbed circulation in the power and resistance of the plantar arch, and in the disturbed mechanism of the lower limb, flat-foot representing functional adaptation. The author gives in detail his reasons for this view, and also goes into the history of the subject.—*Gl'Incurabili*, July 1 and 15, 1900.

The Diagnosis of Neurasthenia.—After enumerating the more common symptoms of the affection and touching upon the chief points of distinction between organic and functional nervous diseases, Gustavus Eliot discusses the differential diagnosis between neurasthenia and hysteria, hypochondriasis, various mental aberrations, and lithæmia. Concerning the differentiation from hysteria he says that the sudden and violent convulsive attacks of hysteria do not belong to neurasthenia, although in the latter disease slight muscular twitching and subjective quivering and throbbing are not uncommon. The globus hystericus is common in and characteristic of the disease whose name the symptom bears, but is rare in neurasthenia. The symptoms of hysteria are characterized by violence and activity. Those of neurasthenia are of a less obtrusive character. They are more quiet and subdued. Hysteria is seen in individuals of emotional temperament, whose mental organization is not well balanced, while neurasthenia very commonly affects the intelligent and intellectual. Finally the symptoms of hysteria very frequently disappear early and completely, leaving the patient in usual health, while neurasthenics recover slowly and gradually.—*Yale Medical Journal*, September, 1900.

Bronchial Asthma; its Relation to Nasal Disease.—H. L. Swain discusses the various theories of the causation of asthma, believing it to be due to a spasm of the muscular fibres which encircle the point where the terminal bronchus ends and opens out into the atrium. When this narrow opening into the larger sac is suddenly contracted by a spasm the respiratory space beyond the terminal bronchus becomes more and more stretched. Hence the lobule corresponding to the space becomes distended, and this occurring all over the pulmonary structure, we have the familiar distention of the chest. The exciting cause of this spasm may come from the intra-nasal condition, but even here we must have an explosive nerve tendency, lack of vasomotor control, and thin-walled veins which are present in some individuals but absent in others. Given this combination of factors, a cause operating through any one of various organs may excite an asthmatic attack. The nasal condition is only one of the factors which may initiate the bronchial spasm.—*Yale Medical Journal*, August, 1900.

The Use of Diphtheria Antitoxic Globulins of the Blood Serum Instead of the Entire Serum in Diphtheria.—W. H. Park, in an attempt to isolate the globulins which are closely connected with the antitoxic substances in the blood, has carried out a series of experiments. The antitoxic globulin secured has been tried with a view of obviating the toxic manifestations, rashes, etc. The results are disappointing, and there seems no probability of separating the antitoxic properties from the globulin. This the author thinks probably true of other protective serums.—*Pediatrics*, August 15, 1900.

Critical Review of the So-Called Physiological Theory of Emotion.—Charles A. François-Franck combats the notion held by many modern psychologists, that the circulatory disorders accompanying mental emotions and disturbances are their cause; that the brain is in reality a mere servant or passive agent of arterial pressure and the general circulation. He adduces many reasons and experiments to prove that, on the contrary, emotional excitement, whether directly cerebral or generally sensory, produces the active congestion of the brain, which always precedes elevation of arterial pressure, and can therefore not be due to it.—*Bulletin de l'Académie de Médecine*, August 14, 1900.

Enlargements of the Spleen in Children.—Samuel West draws attention, in the splenic anæmia of infants, to its chronic course, to its very varying prognosis, and to the fact that syphilis is occasionally, and rickets frequently, associated with it. The association is in neither case constant, nor is either of these diseases the sole cause—probably not the cause at all except indirectly by means of the ill health to which either leads. As to relation between the splenic enlargement and the anæmia, it is very likely that both are due to a common cause. The treatment should be that of anæmia. In regard to other forms of splenic enlargement in children the author calls attention to the frequency in the very young of malaria, leucocythemia, and Hodgkin's disease.—*Medical Press and Circular*, August 22, 1900.

On Convulsive States in General.—A. Pierret says that the convulsive movements of cortical origin may be simply motor disturbances, as in Jacksonian epilepsy, or exclusively sensory, as in sensory epilepsy, but they may also involve the entire brain, in which case their dynamic state is such that consciousness is temporarily affected. This constitutes the epileptic coma with amnesia; at other times consciousness is but partially inhibited. The particular variety of the affection depends upon the state of impressionability of the cells, and on the conditions which, by forming an obstacle to the establishment of equilibrium of nervous tension, favor local hypertension. These two factors may be modified in thousands of ways. When the cortex is involved in the shock, phenomena make their appearance which the spinal cord, or even the

medulla oblongata, is incapable of determining. Cortical epilepsy, even when of the Jacksonian type, is invariably associated with some psychical element, the complete epileptic paroxysm being thus merely the result of blending together the spinal, medullary, subcortical, and cortical convulsive phenomena. The latter may also exist alone, and in this case various simple or complex acts, sensory aura, delirium, hallucinations, vertigo, perverted impulses, or even crimes become the morbid equivalents of the lacking motor convulsion.—*The Medical Press and Circular*, August 22, 1900.

The Functions of the Cerebellum.—R. Gatta from the results of physiological experiments concludes: (1) That clinically the cerebellar complex of symptoms is often rendered multiform by phenomena of compression and irritation of adjacent or peripheral organs (pons, bulb, cranial and cerebral nerves). (2) The cerebellar alterations or phenomena, whether clinical or experimental, are more marked on the side of the lesion. (3) Complete destruction of the cerebellum in animals determines phenomena of ataxia, asthenia, and atony, just as do lesions of the cerebellum in clinical practice. In the experimental cases these symptoms persist, although in attennated form. (4) In the absence of rapid infiltrating action and diffusible toxæmic powers, these experimental pathological processes may continue for months and years. (5) The results of the author's experimentation are in harmony with those already obtained experimentally in regard to the functions of the cerebellum and its relations to the locomotor apparatus.—*La Riforma Medica*, August 6 and 7, 1900.

Evil Results following Abdominal and Pelvic Surgery, and the Measures Requisite to Prevent or Counteract Them.—E. Stanmore Bishop directs attention to the perfection of small details in common surgical work. The utility of early operation in fibromyomata before secondary changes have occurred is discussed. Evil results are avoided by attention paid to the small points in technique. Bad results follow delay, delay is produced by knowledge of former bad results. Among bad results are death, ventral hernia, sinus, vaginal prolapse, intestinal adhesions, persistent pain, and prolonged invalidism. Operation should be done if pyosalpinx, or pressure on the ureters, great loss of blood, development into the broad ligament, or possibility of necrosis is threatened. The mortality will be low if operation is done to forestall these conditions. The bowels should be well cleared out before operation. The small intestines should be incited to action immediately after, not in order to empty itself but because we wish to produce and maintain intra-peritoneal currents which shall carry all stray micro-organisms rapidly away from points where they may develop, into the lymphatics and glands where they will be consumed by phagocytes. Gravity should be made to aid in this matter by elevation of the foot of the bed. Cases so treated are cited. Many of the evil results are avoidable. The causes of hernia production are discussed, and the rational suture to prevent its occurrence is given. A variety of evil results and the precautions necessary in order to avoid them are given.—*The Scalpel*, August, 1900.

A New Theory in Regard to Concussion of the Brain.—D. B. Roncali sums up his article as follows: (1) In grave cases of concussion speedily becoming fatal, the shock to the cells of the cerebro-spinal axis and of the bulb causes so great a molecular disturbance that the individual neurons become incapable of regulating the nutritive and dynamic exchanges, which results in a suspension of the nutritive and secretory functions, causing violent death of the neurons from lack of nourishment and from intoxication, and for this reason there is complete absence of any lesion in the nerve tissue. (2) In cases of concussion in which recovery occurs in a few hours or days, and in which the nerve cells show the lesions described by observers, there is a transitory suspension of the nutritive and dynamic exchanges with temporary suspension of nourishment, and a transitory intoxication. The neurons appear to be in lethargy; their cellular body is shrunken, and there is retraction of the prolongations and fusion of the chromatic substances. According to the author's theory, with retraction of the protoplasmic prolongations there comes absence of nerve-protoplasmic contact and contact between the individual neurons; conduction of impulses to or from the cells is prevented, and nerve waves are impossible, the result being a temporary suspension of the vital functions.—*Il Policlinico*, July 15, 1900.

Echinococcus Cysts of the Domed Surface of the Diaphragm; Removal; Cure.—Edmondo Berger reports the case of a man aged forty years, in whom a tumor as large as a fœtal head was found between the left hypochondrium and the epigastric region, non-continuous with any abdominal organ, sinking with inspiration, rising with expiration, and subject to rhythmic pulsations. Exploratory puncture brought out a fluid containing echinococci. Operation revealed a multiple cyst on the under surface of the diaphragm. The patient made a good recovery. The cause of the cyst was probably a heavy fall upon the nates, the shock being carried up to the diaphragm. The pulsation observed in the cyst was undoubtedly transmitted from the heart.—*Gl'Incurabili*, August 1 and 15, 1900.

The Therapy of Chorea.—W. v. Bechterew considers that the action of arsenic in this disease depends on its power of reducing reflex excitability, basing his views on experimental evidence which shows that the primary increase in irritability is succeeded by a secondary blunting of the centres. In accordance with this theory he combines sedatives with the arsenic, giving the latter in the form of Fowler's solution or as a solution of arsenious acid in doses which are rapidly raised to twice or even three times what is usually accepted as the maximum. At the same time sodium or potassium bromide and antipyrin are given in large doses, while the relationship between rheumatism, endocarditis, and chorea is a sufficient indication for the routine use of the salicylates in conjunction with the other remedies. When the heart lesion actually exists cardiacs are administered. Warm baths and rest in bed are also valuable adjuvants.—*Centralblatt für Nervenheilkunde und Psychiatrie*, August, 1900.

The Prophylactic Douche.—O. S. Chapman says that in regard to this measure there are two classes of observers whose results are absolutely contradictory, but the weight of testimony since the report of Krönig in 1894 seems to be in favor of discarding the douche. Doubtless the vaginal secretions may contain a great variety of bacteria, but they are non-pathogenic, or produce only a moderate rise of temperature. The secretions are more or less bactericidal in character; they provide nature's barrier against the entrance of deleterious germs into the circulation, and to remove them is held to be unwise. Severe puerperal fever and death are generally held to be due to infection from without, which is usually because of neglect of aseptic precautions on the part of the attendant. Free catharsis aids in the elimination of bacteria from the system. The author is of the opinion that the bacteria will meet with more timely neutralization without the preliminary douche than with it.—*Annals of Gynæcology and Pediatry*, September, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, October 6, 1900.

THE NOMENCLATURE OF INFLAMMATION.

INFLAMMATION has always been a difficult condition to express in a word so distinctive as to convey to the mind of the scientific man a clear and accurate definition. Even in the days gone by, the term was vague to a certain degree. But since the marvellous advance made in pathology within recent years, the situation in this respect is so infinitely worse that, without much exaggeration, it might be described as almost a state of chaos. Any man who can point a path out of the difficulty will be deserving of the heartfelt thanks of the entire medical profession. However, it requires the possession of a large amount of courage and a firm conviction in one's own opinions, to take upon one's self the part of reformer, be the projected change medical or otherwise.

Most people, including the members of the medical profession, who after all are but human, when once settled in a groove and accustomed by the force of habit to a certain routine, are by no means thankful to the earnest and well-meaning person who is wishful to lead them into the right way, and are apt to regard him as a decidedly officious and troublesome individual. With regard to the term inflammation, there has been for some time more than a suspicion, which is gradually changing to a certainty, that it is not the right word in the right place, and one or two eminent scientists have thrown out strong hints to this effect in order, probably, to feel the pulse of medical opinion on the matter.

A wonderful change has passed and is passing over the science of medicine as regards the etiology of disease. Maladies of all kinds are year by year being referred to specific causes. Those which were formerly regarded as simple inflammations, in order to distinguish them from general diseases, are now placed in their correct category. Pneumonia but a short time since was esteemed one of the most typically local diseases, although it has now been demonstrated to be due to streptococcic origin. Erysipelas again, though still looked upon by some as a simple inflammation, is held by the larger number of investigators to be owing to a distinct microbe. The term meningitis includes a whole class of varying forms of the malady, none of which can be called simple; and the list can be lengthened almost indefinitely. Dr. Payne, in his address on pathology before the British Medical Association in 1898, touched on all these points, and remarked pertinently that it was becoming a question whether every organ of the body had its inflammation denoted by a name ending in itis. This being the case, it is contended by many that the time has come to alter the appellation of inflammation, and to bestow upon conditions of disease names truly expressive of their real nature. But, as said before, it takes a man of courage even to recommend a change in the established order of things. A few have done so with regard to the term inflammation, although in most instances somewhat timorously; and by none has the present position of affairs and the need for revision been put so boldly and clearly as by Dr. Andrew H. Smith, of this city.

Dr. Smith contributed a paper, published in the Transactions of the Association of American Physicians, on this subject, which is full of good points. After giving a lucid explanation of the phenomena of inflammation as now conceived and indeed established, he urges that the terminal itis be dropped. He shows that, speaking of what is known as the inflammatory process in injuries as a matter of fact, the most recent American authorities are by no means agreed as to what manifestations are to be included in the inflammatory process, and what are to be left without the pale. Thus in Park's "Surgery," by American authors, the term inflammation is restricted to those disturbances which are produced by bacteria themselves or by their toxins, and which tend to pus formation. Nancrede holds a similar view and entitles one of his lectures "Inflammation a True Microbic Process." Dr. Smith suggests that as most of the phenomena heretofore included under the term "inflammation" are manifestations of the local action excited by a micro-organism or by a poison circulating in the blood, such action be expressed by a termination to be affixed to the name of the organism or poison if the same can be determined, or to the organ or part affected in case the particular infecting organism or poison is not identified. He aptly cites as a precedent for the first-named use the case of tuberculosis. Dr. Smith contends that no word ought to be made to include all the heterogeneous unrelated precursors and conditions which have been comprised under the term "inflammation," and that the phenomena ascribed to the inflammatory process should be assigned to new relations in accord with recent advances in pathology, and especially in bacteriology.

He further would have us adopt traumosis in place of inflammations from wounds and injuries, toxosis in lieu of inflammations from poisons, and bacteriosis to denote inflammations from the action of micro-organisms. We are thus presented not only with bold etymological innovations, but the whole trend of Dr. Smith's argument is of an iconoclastic strain, which a less courageous man would have hesitated to advance. If the medical profession should accept these views with half the enthusiasm and earnestness with which its author is imbued in putting them forth, the gain would be considerable. For so long as inflammation is treated as a disease with the chief object of combating its more conspicuous manifestations, heat, red-

ness, and pain, which are now not even regarded as essential to its conception, the physician is too much given to lose sight of the true etiological factor. Dr. Smith points to the greater success in the management of appendicitis since the bacterial origin has been recognized and the antiphlogistic treatment has been abandoned, as an apropos illustration of this proposition.

Although physicians are ever becoming more and more pervaded by the enlightened spirit of the times, yet the shadow of antiquated pathology still obscures the clearer conception of inflammation reached by modern research. Dr. Smith's courageous arraignment of the inappositeness of the term inflammation as used now is a valuable contribution to latter-day scientific literature, which should embolden those less fearless to follow his sagacious lead into this interesting field of inquiry. The most valuable outcome from the propagation of the view that inflammation is in no proper sense a new force projected into the arena, a disturbing influence, an enemy to be dreaded, a disease to be "treated," will be that its treatment will be abandoned. The cause of the true malady will be sought out, and when found attacked. The direction of modern therapeutics, too, tends toward the method of not treating the disease so much as the patient in acute infectious diseases. Attention was drawn to this truth in a paper recently published in the MEDICAL RECORD. If Dr. Smith's conclusions, and the conclusions of those who have written to the same end but have not stated the case so strongly, are accepted, their papers will serve a most beneficial purpose, and should pave the way to a more enlightened therapy. Since the latter is the very essence of the physician's life work, the importance of the theme cannot be overestimated.

A VERIFICATION OF THE MOSQUITO-MALARIA THEORY.

WE have referred several times to the interesting experiments which some English observers had undertaken during this summer in the hope of definitely verifying or disproving the mosquito theory of the spread of malaria. These experiments were to be conducted both in Italy and in England. That in Italy, which is still going on, consists in the residence of several men in one of the most malarious parts of the Roman Campagna, near Ostia, drinking the water and exposed to the night air, taking no quinine, and protected only from the bites of Anopheles, the malarial mosquitos. We learn from the *British Medical Journal* of September 22d, that it is highly probable this experiment will be successful. A telegram to Dr. Manson from Professor Grassi, dated September 13th, stated that the health of the experimenters had, up to that time, remained perfect. Certainly, if these men (Drs. Sambon and Low, and Signor Terzi, with their servants) escape malaria, we shall have negative evidence of much value to the effect that malaria is not conveyed by the water or the air.

The other experiment, which has just been concluded in England, has furnished us with very positive and conclusive evidence of the part played by mosquitos in the transmission of this disease from the sick to the well. In a leaflet inserted in the *Journal of Tropical Medicine* for September, 1900, it is stated that the experiment of inoculating malaria in England by mosquitos fed on malaria patients in Rome has succeeded. "At Dr. Manson's request, three batches of Anopheles were fed in Rome by Dr. Bastianelli on three separate malarials (tertians) and forwarded in cages to the London School of Tropical Medicine. Dr. Manson's son, P. Thurburn Manson, was bitten every second day by the insects until they died—usually about ten days after their arrival in London. The first batch was fed in London on the first and second week of July, the second at the end of August, and the last during the second week of this month. The subject of this experiment remained in perfect health till the morning of September 13th, when headache, bone-ache, lassitude, and anorexia, with rise of temperature to 102°, set in. On the 15th there was a distinct intermission during the forenoon. High fever, 104°, set in about 4 P.M., with delirium, relieved during the night by profuse diaphoresis. The same series of events recurred on the 16th. On the morning of the 17th, tertian parasites were found in the blood."

The editor of the journal from which we have quoted adds to this account that he has himself seen the parasites, and that Dr. Manson has been careful to have the observation verified by several competent observers. This is unquestionably the most conclusive of the inoculative experiments yet made, for the possibility of infection by other channels, which was present in the Roman experiments, and to a less degree in a similar one which we understand was carried out in New York this summer, was here eliminated. Dr. Manson's son could not get tertian fever in London in any ordinary way, and he had not been in a malarious country since his childhood, therefore there can be little room for doubt as to the agency of the imported mosquitos in the causation of his illness.

THE CHICAGO DRAINAGE CANAL.

IN the *Review of Reviews* for January is an article by Professor Edwin O. Jordan, bacteriologist in the University of Chicago, upon the Chicago drainage canal. The article in question is moderate in tone and conservative in views, the author expressing his belief that the dilution with so large a body of water and the great distance (above three hundred miles) in which the stream will have time to clear itself will render it harmless before reaching St. Louis, but the admission is made that a "thoroughgoing chemical and bacteriological examination, both before and after, is the only way by which the questions relating to the public health can be satisfactorily and conclusively answered. If it should be found on impartial inquiry, after the canal has been put into operation, that danger, inconvenience, and loss are resulting to other communities, ways must be found to remedy these difficulties." This is the ordinary attitude nowadays with regard to pollution of water supplies—pollute

first and inquire afterward, probably when it is too late to alter to any great extent the existing insalubrious conditions. The wholesale and careless contamination of streams and water supplies generally is an ever-growing evil, and the time has come when the public must insist in self-defence that very much more stringent laws than those relating to the matter now in force must be introduced and strictly carried out. It may be in the case of the Chicago canal that at such a distance purification by natural means may take place, and that when St. Louis is reached the canal may at least not be a menace to the health of the inhabitants of that city. So far, however, as the properties of streams or rivers purifying themselves is concerned, it has been proved on many occasions that at all times a much longer distance than was formerly held to be needful is necessary. Also this is a matter in which the character and amount of contamination and the flow of water must be taken into account.

The fact is incontrovertible that the hurtful and alarming conditions which have been brought about by a stupid and careless disposition of sewage and wastes of mines and mills is so evident that examples of the baneful results abound on every side. Mr. Henry Talbot, in a pamphlet recently published by him on the pollution of water supplies, makes use of the following strong but justifiable language: "The streams have been made sewers through selfishness, and it is through selfishness alone they can be redeemed and purified." The people of St. Louis are undoubtedly well within their rights in objecting to the health of their city being menaced by the Chicago canal. The suggestion of Professor Jordan should be promptly acted upon, and steps taken to test its reputed unsavory waters.

News of the Week.

Philadelphia County Medical Society.—At a stated meeting held September 26th, Dr. M. J. Karpeles presented a communication entitled "Imperforate Hymen with an Interesting History," and Dr. Joseph Price read a paper on "Delayed Operations in Appendicitis."

The Pathological Society of Philadelphia.—At a stated meeting held September 27th, Dr. Joseph McFarland presented a communication entitled "Experimental Tuberculosis in Cats," detailing the results of injections of "avian," "bovine," and "human" tubercle bacilli. Dr. W. Wayne Babcock presented a specimen of multiple pregnancy in association with fibromyoma of the uterus, and also sections from a case of retroperitoneal (?) endothelioma.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee.—The twelfth annual meeting of this society will be held in Chattanooga on Thursday, Friday, and Saturday, October 11, 12, and 13, 1900, during the reunion of the Army of the Cumberland and the Spanish-American war veterans. A rate of one fare for the round trip will doubtless be given the latter from all parts of the country. The Southeastern Passenger Association has already given this rate, and the other associations will take up the matter shortly. A large attendance is expected and a good programme is in prospect. All desiring to present papers should send the title to the secretary, Dr. Frank Trester Smith, of Chattanooga.

A Death from Anthracene.—A woman died in this city recently in violent convulsions. Investigation showed that she had committed suicide probably by taking a mixture of morphine and anthracene, a prescription calling for which was found in her room. Anthracene is a coal-tar product occurring under the form of colorless fluorescent crystals. It is the base from which alizarin dyes are made.

Cremation in Spain.—A new sanitary law which is now under consideration in the Cortes, having already passed the upper house, removes the ban of illegality which has hitherto, through the influence of the church, rested upon the practice of cremation in Spain. In anticipation of the passage of this law a cremation society has recently been established in that country.

By the Will of the Late Dr. J. M. Da Costa, formerly professor of the practice of medicine and of clinical medicine in Jefferson Medical College, the sum of $5,000 is devised to the Pennsylvania Hospital for the endowment of a free bed, an equal sum to the Children's Hospital, likewise for the endowment of a free bed, in memory of his son, John M. Da Costa; $5,000 to the College of Physicians of Philadelphia, for the endowment of a publication fund; $5,000 to the University of Pennsylvania for the professors' retiring fund. His valuable and extensive medical museum, including charts, models, medical pictures, and drawings, is bequeathed to Jefferson Medical College. His medical library, containing many good books, is bequeathed to the College of Physicians of Philadelphia.

Prognosis of Yellow Fever in Havana.—A telegram from Havana to *The Sun* says that the statement was made recently in a local paper that forty-five per cent. of the Americans attacked by yellow fever died. In reply to this Dr. Gorgas, who came here under direction of the Marine-Hospital service, has written a letter to the journal referred to, in which he says that during the year 1900 up to and including the 12th of September, out of a total of one hundred and nine American cases there were nineteen deaths. Sixty-six of these American cases were treated at the Las Animas Hospital, and there were only six deaths. Dr. Gorgas says that his object in correcting the statement is to relieve Americans from the feeling that forty-five per cent. of them are bound to die if attacked by this disease. Under favorable circumstances ninety-one out of every one hundred attacked recover. This is not guesswork, but is shown by actual statistics.

Infectiousness of Tuberculosis.—The supreme court of Michigan has recently decided that physicians must obey the injunction of the State board of health to report all cases of tuberculosis coming under their

cognizance. A medical man of prominence had disregarded this requirement, insisting upon his right to do so because tuberculosis was not expressly mentioned in the statute. The lower court excused him on this ground, but the supreme court has reversed this decision, holding that the State board has the discretionary power to classify pulmonary consumption among contagious or communicable maladies.

Professor Th. Escherich of the chair of pediatrics has been elected dean of the medical faculty of the University of Graz for the academic year 1900–1901.

Dr. James Musgrove has been appointed the first professor to the new chair of anatomy established and endowed by the Marquis of Bute at St. Andrews University by a gift of £20,000 for the purpose.

The Famine in India.—Some idea of the great calamity which has visited India in the failure of the crops through lack of rain is to be had from a report of the viceroy of India, according to which the number of persons receiving relief at the beginning of September was 4,891,000.

Satisfactory Health Conditions in Santiago.—Although yellow fever has been rather more than usually troublesome in Havana this summer, no case of the disease has been reported in Santiago since December. This good showing is attributed to efficient sanitary administration inaugurated by General (Dr.) Leonard Wood and maintained by Col. Samuel M. Whiteside, commander of the department of Santiago and Puerto Principe. One hundred miles of streets are swept daily and previously infected houses have been three times disinfected. A house-to-house inspection is made by the surgeons, and thousands of gallons of carbolic acid and tons of chloride of lime have been used.

A Vaccinator Charged with Assault.—A physician in New Bedford, in the course of his duties as vaccinator of the board of health, visited a house in which he found a six-year-old boy who had not been vaccinated. He thereupon vaccinated the lad without any objection on the part of the mother, who, however, remarked to him at the time: "You won't have to vaccinate my baby, will you?" The doctor answered that he thought he would, and in response to further objections by the mother told her that she would have to settle them with the board of health. He then proceeded to vaccinate the baby, a child five months old. Some time later he was more surprised than pleased to be dragged into court on a charge of assault and battery. It was proved without contradiction that the mother, notwithstanding her remonstrances, bared the infant's arm for the operation; and the court acquitted the defendant on this ground, holding that it was convincing evidence that the complainant, although undoubtedly reluctant, had finally consented that the child should be vaccinated.

A Course of Hospital Economics at the Teachers' College.—At the request of the American Society of Superintendents of Training-Schools for Nurses, the authorities of Columbia University will establish this fall a special course in "Hospital Economics," to be given at Teachers' College. The aim of the course is to fit persons who are already trained nurses for the responsible duties of superintendents of hospitals and principals of training-schools for nurses. It is intended to present the practical problems of hospital administration and to give students systematic instruction in the organization and management of training-schools. The prescribed course of study will include general psychology and its application in teaching; methods, practice, organization, and supervision of hospitals and training-schools, biology, physiology, hygiene, the production and manufacture of foods, home sanitation and management, bacteriology, and household chemistry. Special researches will also be made on the subjoined topics: Laboratory preparation of culture media, isolation and culture of bacteria, preparation of antitoxins; milk laboratories, modified milk, sterilized milk, pasteurized milk, dairies, source of bacteria in milk, effects of bacteria in milk; general hospitals, private hospitals, special hospitals, training-schools, small general hospitals, insane asylums, dietary on a scientific basis in an insane asylum, operating-theatre, sterilizing-plant, preparation for operation, detail work of clinic, philanthropic organizations, relations of the nursing-professor.

American Public Health Association.—The twenty-eighth annual meeting of this society will be held at Indianapolis on October 22, 23, 24, 25, and 26, 1900, under the presidency of Dr. Peter H. Bryce, of Toronto. The following subjects will be discussed: The Pollution of Public Water Supplies, The Disposal of Refuse Material, Animal Diseases and Animal Food, Car Sanitation, Etiology of Yellow Fever, Steamship and Steamboat Sanitation, Relation of Forestry to the Public Health, Demography and Statistics in their Sanitary Relation, Cause and Prevention of Infectious Diseases, Public Health Legislation, The Duration of Infectious Diseases, Cause and Prevention of Infant Mortality, Disinfectants, Municipal Sanitary Administration, To Define What Constitutes an Epidemic, A National Leper Home, Dangers to the Public Health from Illuminating and Fuel Gas, Revision of Bertillon Classification of Causes of Death, Transportation of Diseased Tissue by Mail, The Teaching of Hygiene and Granting of Degrees of Doctor of Public Health, and Sewerage and Water Supply. Special attention will be given to the engineering phase of the last-named subject.

Examination for Acting Assistant Surgeon in the Marine-Hospital Service.—The United States Civil Service Commission announces that on October 23 and 24, 1900, an examination will be held in any city in the United States where it has a local board of examiners, for the position of acting assistant surgeon in the Marine-Hospital service. The examination will consist of the subjects mentioned below, which will be weighted as follows: Letter writing, 5; anatomy and physiology, 15; surgery and surgical pathology, 20; chemistry, materia medica, and therapeutics, 10; bacteriology and hygiene, 10; theory and practice of medicine and general pathology, 25; obstetrics and

gynæcology, 15; total, 100. The examination will be divided into two days of seven hours each. Applicants for this examination must be competent physicians and surgeons, graduates of reputable medical colleges, and must furnish satisfactory certificates relative to their moral character and ability. From the eligibles resulting from this examination it is expected that certification will be made to the position of acting assistant surgeon, United States Marine-Hospital service, at Juneau, Alaska, and for similar vacancies as they shall occur. This examination is open to all citizens of the United States who comply with the requirements and desire to enter the service. All such persons are invited to apply, and applicants will be examined, graded, and certified with entire impartiality and wholly without regard to any consideration save their ability as shown by the grade attained in the examination. It is the practice of the department, however, whenever practicable, to appoint a regularly practising physician residing at the place where the vacancy exists. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and promptly forwarded to the commission.

Decreasing Infant Mortality in New York City.—Although the summer just passed was one marked by excessive heat and humidity, almost without a break for three months, the infant death rate was less than for any year in the past decade. The following table is made up from the statistics of the board of health:

Deaths and Death Rates of Children Under Five Years of Age, for the Months of June, July, and August.

	Population.	Deaths.	Death Rate.
1891	188,703	5,945	126.0
1892	194,214	6,612	136.1
1893	199,886	5,892	117.9
1894	205,723	5,789	112.6
1895	212,983	6,183	116.1
1896	216,728	5,671	104.7
1897	220,641	5,401	91.3
1898	224,736	5,047	89.8
1899	229,029	4,689	81.8
1900	233,537	4,562	78.1

It is claimed by those who are interested in the Nathan Straus booths for the distribution of pasteurized milk that this good showing is largely due to this establishment. The first sterilized-milk booths were opened in 1893, and the infant death rate has almost steadily declined since then. No doubt this is one of the causes, but we are inclined to the belief that to the late Colonel Waring belongs much of the credit for this saving of life, for the progressive decrease in the infant mortality really began with the cleaning of the streets effected by that noble citizen.

A Testator Objects to Chaplains.—It is stated in the *National Hospital Record* that a recent bequest of $50,000 to the Geneva, N. Y., City Hospital contains a peculiar clause, stipulating that the hospital "shall not have an officer known as a chaplain or have any person in its service at any time any part of whose duties it shall be to perform such services as are usually performed by a chaplain." The will provides that in case the request is not complied with such bequest shall revert to the estate of the testator and then be given to the Rochester City Hospital. Not more than $10,000 of the sum is to be expended for buildings.

Medical Fraternities for Women.—We are requested by a member of "Zeta Phi" to state that this society is not the first and only woman's medical fraternity, there being one and possibly more in western medical colleges.

Trinity Infirmary, which has been closed since last spring, will be reopened about the middle of this month. The hospital was formerly under the charge of the Episcopal Sisters of St. Mary, but will in future be under the management of a woman superintendent and a staff of lay nurses.

The Plague still lingers in Glasgow. There were two deaths on September 29th, one of them being of an infant born of a woman suffering at the time from the disease. Up to the first of this month there had been seven deaths, and twenty-one cases were still under treatment.

Insanity of a Christian Science Convert.—A young woman physician, formerly practising in Concord, is confined at the New Hampshire Asylum for the Insane under treatment for melancholia, which began to show itself shortly after she embraced the teachings of Christian Science and relinquished the practice of her profession.

Ptomain Poisoning at a Dental Dinner.—Twenty-four dentists, members of the Delta Sigma Delta fraternity in Chicago, attended a banquet of the society on September 28th, and more than half of them presented serious symptoms of ptomain poisoning during the night. The poison is believed to have been contained in some canned salmon.

A Collective Investigation of Cancer in Prussia.—The Prussian government has sent a circular to all practising physicians in the kingdom calling for answers to a series of questions bearing upon the etiology of cancer. The principal points are whether cancer is hereditary and contagious, whether it is connected with a particular habit such as indulgence in alcohol, tobacco, etc., and whether it is more prevalent in one town or province than in another.

Scarlet Fever at a Health Resort.—It is reported from Quebec that many members of the large American colony at Murray Bay, the watering-place of the lower St. Lawrence, have been placed in quarantine on account of the outbreak of scarlatina in their families, and they are unable to leave for home. The family in which the first case of scarlatina occurred had made purchases of homemade Canadian rugs, homespun cloths, etc., manufactured by the local French-Canadian housewives, and these are believed to have carried the infection. The rapid spread of the disease is attributed in part to the promiscuous use by

visitors of the calashes, or peculiar two-wheeled public conveyances. All these are now being disinfected.

Evidences of the Coal-Miners' Strike have darkened the sky of this city during the past two weeks, for many establishments have begun to use bituminous coal and their chimneys have sent forth great clouds of black smoke. No doubt it would have been even worse but for the action of the health department in causing the arrest of many of the offenders. There is no law, we believe, against the burning of soft coal, but only against permitting the smoke thus formed to escape.

A Valued Diploma.—A physician in Brooklyn nearly lost his life a few days ago while attempting to save his diploma of the College of Physicians and Surgeons from his burning residence. A few minutes after the doctor had been aroused and had reached the street he rushed back into the burning building for his diploma, which was in a room on the second floor. He succeeded in finding it, but while groping about the lower vestibule was overcome by smoke. He was found unconscious on the floor and dragged to the open air, where he was revived. The diploma was recovered, after the fire had been extinguished, near the spot where the doctor had fallen unconscious.

Insanity at the Elmira Reformatory.—It is reported that in the past six months sixty-five inmates of the State Reformatory at Elmira have been transferred to the Matteawan State Hospital for the Insane. Some of the young criminals at the reformatory develop symptoms of insanity and are transferred to the asylum every month, but this is greatly in excess of the usual number. It is noteworthy that this increase is for the period following the resignation of the former superintendent, concerning the alleged brutality of whose administration there was such an outcry in the sensational newspapers.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 29, 1900. September 21st.—Assistant Surgeon M. K. Elmer detached from Boston navy yard, ordered to accompany battalion of marines to Mare Island, then to duty on *Ranger*. Assistant Surgeon J. C. Thompson detached from *Newark* on reporting of relief, to proceed home and wait orders. Assistant Surgeon W. B. Grove ordered to duty on *Vermont*. Assistant Surgeon H. E. Odell detached from *Ranger* on reporting of relief, and ordered to Asiatic station with battalion of marines for duty as relief of Assistant Surgeon J. C. Thompson. September 24th.—Surgeon B. F. Stephenson detached from the *Baltimore* when out of commission, ordered to examination for promotion at Washington navy yard, October 1st, thence home and wait orders. Assistant Surgeon W. H. Bell relieved from additional duty at Norfolk Hospital, and ordered to continue duty on the *Vixen*. September 25th.—Assistant Surgeon H. A. Dunn, order of September 22d modified, ordered to report for duty on *Dorothea* October 1st, instead of proceeding home. September 26th.—Assistant Surgeon K. Ohnesorg detached from the Naval Academy and ordered to the *Vicksburg*. Assistant Surgeon A Stuart detached from the *Fortune* and ordered to resume duties on the *Yankton*. Assistant Surgeon E. V. Armstrong ordered to report to commandant of New York navy yard for duty on *Vermont*. September 27th.—Medical Director C. U. Gravatt commissioned medical director from August 24th. Surgeon G. B. Wilson commissioned surgeon from February 7th. September 22d.—Pharmacist R. Waggener ordered to duty at naval proving-grounds, Indian Head, Md.

Obituary.

SAMUEL SMITH PURPLE, M.D.,

NEW YORK.

Dr. S. S. Purple, whose death occurred on Saturday night, after a brief illness, was one of the last of the generation of New York physicians which included Sayre, Willard Parker, Fordyce Barker, Post, Clark, and others. He was born in Lebanon, Madison County, N. Y., June 24, 1822, and was graduated at the medical department of the University of the City of New York in 1844. In 1846–48 he was physician at the New York City Dispensary, and was ward physician under the board of health during the cholera epidemic of 1849. He was vice-president of the New York Academy of Medicine from 1870 to 1875, and its president from 1876 to 1880. The profession of this city owes to Dr. Purple's generosity the library of the Academy of Medicine, for it was his presentation of four thousand volumes that formed the nucleus of the library which has now grown to such proportions. He is said, notwithstanding this gift, to have owned at the time of his death one of the largest private libraries in New York. Dr. Purple was a prominent member of the New York Genealogical and Biographical Society, and was elected a vice-president of the society in 1888. For a number of years he was senior editor of the *New York Journal of Medicine* until it was merged into the *American Medical Times* in 1860. He followed the active practice of his profession until fifteen years ago, when he retired to enjoy the ease to which he was entitled after his long and busy career.

ALFRED STILLÉ, M.D.,

PHILADELPHIA.

Dr. Alfred Stillé died at Philadelphia on September 24th in the eighty-seventh year of his age. He was graduated from the University of Pennsylvania in 1832, and from its medical department in 1836, when he became a resident physician in the Philadelphia Hospital. After post-graduate study abroad for two years, he became, in 1839, a resident physician in the Pennsylvania Hospital. From 1845 to 1859 he was lecturer on general pathology and the practice of medicine in the Philadelphia Association for Medical Improvement, and from 1854 until 1859 he occupied the chair of the theory and practice of medicine in the Pennsylvania Medical College. In 1864 he was elected professor of the theory and practice of medicine in the University of Pennsylvania, and upon his resignation many years ago he was elected emeritus professor. He became a visiting physician to St. Joseph's Hospital in 1840, resigning this position in 1877. During the Civil

War he was one of the visiting physicians to the United States Satterlee Hospital. He was from 1865 to 1871 one of the physicians to the Philadelphia Hospital. He was one of the founders of the American Medical Association and a member of many scientific bodies, in several of which he at times held important offices. He was a prolific writer, being among other things co-editor of the United States Dispensatory, co-translator of Andral's "Pathological Hæmatology," and author of "Elements of General Pathology" and of "Materia Medica and Therapeutics."

Obituary Notes.—Dr. S. Potts Eagleton, formerly of Philadelphia, died at Ocala, Fla., on September 18th, at the age of thirty-three years. He was graduated from the University of Pennsylvania in 1890.

Dr. Jesse W. Lazear, acting assistant surgeon in the United States army, died of yellow fever in Cuba on September 25th. He formerly practised in Baltimore, and was a graduate of the College of Physicians and Surgeons in New York City in the class of 1892.

Progress of Medical Science.

Journal of the American Medical Ass'n, Sept. 29, 1900.

Etiology of Scarlatina.—William J. Class considers the evidence in favor of the view that the diplococcus scarlatinæ is the cause of scarlet fever. This organism is a new germ. Its presence in cases of the disease has been well proved. Gradwohl found it in seven consecutive cases and Jaques in every one of a large number of cases examined. The writer in 1899 had found it in three hundred successive cases of scarlet fever and scarlatinous sore throat. It is pathogenic for mice, swine, and guinea-pigs. Scarlet fever can be reproduced in animals by the diplococcus scarlatinæ, and the pathological changes resemble those of scarlet fever. The disease produced by this organism is of a contagious nature. Scarlet-fever blood has an inhibitory action on the growth of this organism. This germ is found in throat secretions of patients with scarlatinous sore throat. The growth of the organism in milk does not affect that medium. The germ is found in cases of surgical scarlet fever.

Gauze Carrier.—Clinton T. Cooke describes this new instrument designed to introduce gauze into cavities in, or orifices of, the body for drainage purposes or for controlling hemorrhage. It will rapidly and often painlessly pack gauze into cavities, wounds, fistulæ, or sinuses. Only one introduction is necessary at one dressing. The gauze is transferred directly from container to cavity, and is not touched by human hands.

Technique of Vaginal Extirpation for Cancer of the Cervix by Ligature Only.—By Rufus B. Hall.

Abdominal vs. Vaginal Hysterectomy for Uterine Carcinoma.—By John B. Deaver.

Importance of Early Recognition of Cancer of the Uterus.—By William H. Humiston.

Operative Treatment of Cancer of the Uterus.—By William R. Pryor.

Philadelphia Medical Journal September 29, 1900.

Inhibition of the Heart as an Aid in Diagnosis.—Albert Abrams sums up the following conclusions. 1. The inhibition manœuvre will cause organic cardiac murmurs to become faint, and in exceptional cases inaudible. 2. Transmitted murmurs are more amenable to the manœuvre. 3. The fainter the murmur, the more easily is it suppressed by the manœuvre. 4. When a transmitted murmur can be inhibited, the tone which it masks can be auscultated. 5. Heart tones are less amenable than are heart murmurs to inhibition. 6. Hæmic murmurs are more readily inhibited than are the organic murmurs. 7. As a rule, the murmurs of anæmia may be suppressed and their evanescence is marked by the reappearance of tones. 8. Exocardial murmurs are easily influenced by the inhibition manœuvre. 9. When the inhibition manœuvre is incorrectly executed, the result is to increase the intensity of the murmurs owing to increased exertion which intensifies the force of the heart's action. 10. The manœuvre often repeated gives no results, owing to overstimulation of the vagi. 11. In irregular action of the heart or in delirium cordis, the inhibition manœuvre is valuable in determining the time of a murmur. 12. This manœuvre enables us to determine the condition of the vagi as inhibitors of the heart and is a guide in the administration of cardio-tonics. For clinical purposes, inhibition of the heart, according to the writer's experience, is best attained by voluntary contraction of the muscles of the neck, which, however, must needs be forcible. The manœuvre is readily learned.

On Some Cases of Pleural Exudate, with the Physical Signs of Pneumonia. Herman B. Allyn recounts a case of empyema in a young woman who had been perfectly well till nine days before admission to the hospital. Four days before admission she had been taken with a severe chill, and since had been in bed with fever, cough, pain in the side, and expectoration. The physical signs on admission consisted of flatness on percussion over the left lung, increased vocal fremitus, bronchophony and pectoriloquy, tubular breathing, and some subcrepitant râles at the left base. At the autopsy was found a thickened pleura, with about 250 c.c. of pus, a fibroid lung, with bronchiectasis and old tuberculous foci in both lungs. There was probably just enough air-space above the small layer of pus to act as a resonator for the voice and breath-sounds transmitted through the dilated bronchus. There is evidently no pathognomonic sign of a pleural exudate. The most important test of the presence of fluid in the pleural cavity is puncture with an aspirating-needle. The *x*-rays are of great service in the diagnosis of pleural effusion and of the amount of fluid present.

Pylorectomy for Adenocarcinoma, with Report of a Case.—By Joseph H. Branham.

Some Clinical Effects of Ammonio-Formaldehyde.—By Edward L. Keyes.

A Digest of Two Hundred Cases of Pneumonia.—By C. Z. Weber.

Appendicitis.—By Samuel Lloyd.

Medical News, September 29, 1900.

Some Studies in Metabolism in Chronic Nutritional Disease.—G. W. McCaskey says that in the study of chronic nutritional disease of various sorts, they can be divided into three groups: one with diminished, another with excessive, and a third with normal urea excretion. Out of forty cases of neurasthenia with marked hypoazoturia, the lowest quantity found was 2 gm. in one case, ten cases had 5 to 6 gm., and the remainder ranged from 6 to 19. In cases of hyperazoturia we find numerous chronic morbid states, among which diabetes mellitus occupies a conspicuous position, in which tissue metabolism is excessive, and the output of urea greatly in excess of what it ought to be. In the case of a young girl weighing ninety-five pounds, the quantity of urea was 48 gm. In cases of ortho-azoturia we find the urea excretion strictly within the normal range, and yet have to deal with obvious, chronic, morbid nutritional states; here we commonly have to deal with toxic conditions resulting from functional disturbances of some one or more of the principal organs of the body. In studying the urea excretion a series of analyses of measured twenty-four-hour collections is advisable in all cases in which unusual conditions are met with.

The Art of Keeping Cool, with Special Reference to the Proper Use of Water. Ralph Wait Parsons says that by introducing water in small and frequent quantities either into the stomach or rectum, we can obtain a reduction in the bodily temperature, due to the direct effects of the cooling properties of the water, to reflex action, and to stimulation of the function of the sweat glands. In hot weather, he advocates a dip in water at 60 to 70 F. lasting from one-half to one minute, and followed by a vigorous rub with a coarse bath towel. A shower bath is even better. This cold bath stimulates the heart and nervous system, gives a sense of well-being, gives a healthy glow to the skin, improves the appetite, and rejuvenates the whole organism, giving energy to resist the depressing effects of heat and sultriness. At the close of a hot day, a bath at 103 to 105 F., lasting from three to seven minutes, is cleansing and stimulating; it should be followed by cold water, and after a brisk rub the bather can go to rest, and in the majority of cases enjoy a good night's sleep, although the temperature be very high.

The Dose of Potassium Iodide with Reference to its Untoward Effects upon the Upper Respiratory Tract. Lewis S. Somers calls attention to the frequent production of iodism from small doses, and, in contrast, the comparative immunity which attends the administration of large quantities. In some instances, should congestion of the upper respiratory tract be developed after the administration of small initial doses, the symptoms will disappear if the

drug be vigorously pushed. To avoid unpleasant phenomena, when the drug is given in ascending doses for long periods, it is sometimes useful to administer also other drugs, such as arsenic and belladonna. The chances of unpleasant symptoms are decreased by dilution with water or milk. If potassium iodide is taken in large amounts with little fluid, it is retained much longer in the body than otherwise, whereas if liquids in copious amounts are freely exhibited elimination is facilitated, and at the same time favorable results are obtained.

A Rare Case of Injury to the Membrana Tympani.—Thoman D. Tuttle reports the case of a young girl who had gone to bed with her hair done up with hairpins. She was wakened in the night by a sudden, severe pain in the left ear, and a hairpin was found protruding from the canal and removed with some difficulty. The pin had entered open end first, and had punctured the tympanic membrane. The latter appeared almost black, and bulged slightly. The case was treated on antiseptic principles, and at the end of eight days there was no evidence of injury except a slight congestion of the membrane about the point of puncture, which had healed.

Medicine and Superstition.—By G. W. Guthrie.

New York Medical Journal, September 29, 1900.

Hypertrophy of the Turbinated Bodies and their Relations to Inflammations of the Middle Ear; with Report of Fifteen Hundred Operations.—C. R. Holmes covers in this article familiar ground, saying that his experience has led him to prefer the saw and scissors to the cautery and cold wire snare. He aims to remove as little of the edge of the inferior turbinate as is consistent with the restoration of sufficient breathing-space, and save as much of the anterior end of the bone as possible, inclining the direction of the line of cut upward and backward from the lower edge of the anterior, and so as to include as much as possible of the posterior hypertrophy, the saw having been pushed backward till its blunt point is in the pharynx.

A Case of Ozæna, Probably of Sphenoidal Origin.—The patient of J. W. Farlow showed ozænatous changes in only one nostril. While probing he happened to pass the instrument into what was evidently the sphenoidal sinus. Special attention to the cleansing of this cavity was followed by great improvement of all symptoms.

The Use of Piperazin in Nephrolithiasis.—By C. J. Aldrich.

A Chinese Physician.—By W. E. S. Fales.

Boston Medical and Surgical Journal, Sept 27, 1900

A Critical Review of Thirty Cases of Pyosalpinx.—G. S. Whiteside and W. J. Walton report these cases, some of which were operated on in the Massachusetts General Hospital, others being taken from the records of private cases of Dr. M. H. Richardson, while two of them are the writer's cases. They believe that the gonococcus cannot be proved to be the cause either directly or remotely in as large a number of instances as is generally supposed. Among other organism which they have demonstrated to be the only living microbe present in a considerable number of cases, are the bacillus mesentericus, pneumococcus lanceolatus, bacillus tetragenus, colon bacillus, and streptococcus pyogenes. From this series of cases they draw the following conclusions: The mortality of the operation taken as a whole is sixteen per cent. The greatest dangers to be apprehended are in streptococcus infections from peritonitis, in all drained cases from fecal fistula, in tuberculous cases from extension of the disease to other organs. The authors have inserted tables which help in determining the cause of pyosalpinx and defining the symptom complex of the condition.

Traumatic Joints.—Homer Gage concludes his paper on this subject as follows: (1) All injuries to joints accompanied by loss of function are always attended by more or less laceration of the tissues in or about the joint. (2) The delays in the restoration of function are due in most instances not to any complicating diathesis, but to the changes incident to the repair of these lacerations and their effects. (3) Such delays are best avoided by an early resort to massage and active or passive motions, and are favored by too long a continuance of rest and fixation. (4) When such delays have occurred, they are best overcome by more vigorous and persistent manipulation, supplemented by the application of heat or such other agents as may best stimulate the local circulation and favor the elasticity of the tissues.

Post-Operative Hæmatemesis.—Kenelm Winslow says that this condition occurring without any visible lesion and without any apparent cause is very rare. He believes the etiology to be yet unsolved. Others have suggested ligature of the omentum, also twisting of the same, sepsis, and the use of cocaine as causative factors. He then recounts the history of a case of this nature.

A Study of the X-Ray Plates of One Hundred and Forty Cases of Fracture of the Lower End of the Radius.—By E. A. Codman.

The Lancet, September 22, 1900

Beri-Beri.—C. Bullmore does not believe that beri-beri as it appears in England is either infectious or contagious and regards it as a different malady from that seen in foreign countries. He puts forward the theory that the disease that reaches us is due to an alkaloidal poison fanned into flame by the disarranged digestion of sailors who are kept on improper diet, and in that case by properly dieting the vessels and supplying the captains with iron and digitalis tabloids the disease in all probability would be reduced to a considerable extent if not stamped out.

Some Points about Post-Diphtheritic Paralyses.—B. E. Myers presents a statistical table of thirteen hundred and sixteen cases of diphtheria seen in the Park Hospital Hither Green, during the year 1899. Of this number two hundred and seventy-five showed various paralyses. Four tables are given relating to occurrence as to age, months in which the cases occurred, to cardiac paralysis, etc. Nothing new is presented as regards etiology, course or treatment.

Multiple Warts Cured by Revaccination.—J. D. Staple revaccinated a girl whose hands were covered with warts, there being ninety-four on one hand. The operation was successful, but no effect on the warts followed until seven weeks later, when they began to disappear, leaving temporary white spots. In three months the hands were entirely clean.

Treatment of Some Common Diseases of the Skin.—Address before the British Medical Association by P. S. Abraham.

Some Notes on the Use of Mercurol; a New Remedy in Urethritis.—By R. Guiteras.

A Fatal Case of Poisoning by Paraldehyde.—By L. Drage.
